9 Keywords: pull-apart basin, Retrograde metamorphism, muscovite, North Sea, basin subsidence,
10 transform fault

11
12 **Abstract:**

13 Pull-apart basins are narrow zones of crustal extension bounded by strike-slip faults that can
14 serve as analogs to the early stages of crustal rifting. We use seismic tomography, 2-D ray
15 tracing, gravity modeling, and subsidence analysis to study crustal extension of the Dead Sea
16 basin (DSB), a large and long-lived pull-apart basin along the Dead Sea transform (DST). The
17 basin gradually shallows southward for 50 km from the only significant transverse normal fault.
18 Stratigraphic relationships there indicate basin elongation with time. The basin is deepest (8-8.5
19 km) and widest (~15 km) under the Lisan about 40 km north of the transverse fault. Farther
20 north, basin depth is ambiguous, but is 3 km deep immediately north of the lake. The underlying
21 pre-basin sedimentary layer thickens gradually from 2-3 km under the southern edge of the DSB
22 to 3-4 km under the northern end of the lake and 5-6 km farther north. Crystalline basement is
23 ~11 km deep under the deepest part of the basin. The upper crust under the basin has lower *P*
24 wave velocity than in the surrounding regions, which is interpreted to reflect elevated pore fluids
25 there. Within data resolution, the lower crust below ~18 km and the Moho are not affected by
26 basin development. The subsidence rate was several hundreds of m/m.y. since the development
27 of the DST ~17 Ma, similar to other basins along the DST, but subsidence rate has accelerated
28 by an order of magnitude during the Pleistocene, which allowed the accumulation of 4 km of
29 sediment. We propose that the rapid subsidence and perhaps elongation of the DSB are due to
30 the development of inter-connected mid-crustal ductile shear zones caused by alteration of

31 feldspar to muscovite in the presence of pore fluids. This alteration resulted in a significant
32 strength decrease and viscous creep. We propose a similar cause to the enigmatic rapid
33 subsidence of the North Sea at the onset the North Atlantic mantle plume. Thus, we propose that
34 aqueous fluid flux into a slowly extending continental crust can cause rapid basin subsidence
35 that may be erroneously interpreted as an increased rate of tectonic activity.

36

37 **1 Introduction:**

38 Pull-apart basins, which form by crustal extension parallel to their long axis, provide a window
39 into the deformation of the continental crust. Such basins are bounded by two strike-slip fault
40 strands along their long axis and by one or two diagonal normal faults that connect between the
41 strike-slip fault strands (e.g., [Aydin and Nur, 1982; Crowell, 1974; Garfunkel and Ben-
42 Avraham, 1996]) or are located along a jog in the strike-slip fault (e.g., [May et al., 1993];
43 [Seeber et al., 2006]). Their shape is often rhombic or that of a parallelogram. The depth to the
44 bottom of the extended block and the subsidence rate of the basin are undefined in this kinematic
45 description. One option is for the strike-slip fault strands to curve with depth and merge to a
46 single fault in the middle crust (e.g., [Segall and Pollard, 1980]. Another option is for the
47 separate strike-slip fault strands to extend into the upper mantle, in which case, the Moho is
48 down-dropped [Ben-Avraham and Schubert, 2006]. A third alternative is for the strike-slip faults
49 to terminate against or curve into a mid-crustal detachment (e.g., [Arbenz, 1984; May et al.,
50 1993; Seeber et al., 2006]).

51

52 Sandbox models, ([Wu et al., 2009] and references within), and elastic boundary-element models
53 driven by motion from below [Katzman et al., 1995; ten Brink et al., 1996] have attempted to
54 recreate the 3-D geometry of pull-apart basins. Finite-element thermo-mechanical models using
55 extrapolated laboratory measurements of rock rheology to lithospheric strength [Petrinin and
56 Sobolev, 2006; Petrinin and Sobolev, 2008] have also modeled the subsidence rate and history
57 of these basins. Recent advances in the study of continental extension focused on the role of
58 strain localization and dynamic strength evolution, particularly in the middle crust [Lavie and
59 Manatschal, 2006; Regenauer-Lieb et al., 2008]. These models have not yet been applied to
60 pull-apart basins.

61

62 Here we present observations which suggest a significantly weaker middle crust under the Dead
63 Sea pull-apart basin (DSB) than would be predicted by standard rheological models. The basin
64 (Figure 1) overlies continental crust with a relatively simple thermo-mechanical history. The
65 continental crust of the eastern Mediterranean margin is a Triassic-Jurassic passive continental
66 margin with minor later tectonic activity [Freund *et al.*, 1970; Garfunkel, 1997]. Heat flow in
67 this region is low (45-54 mW/m²; [Eckstein and Simmons, 1978; Galanis *et al.*, 1986]) and the
68 narrow dimension of the basin (~10 km) assures that elevated heat flow as a result of extension
69 dissipates rapidly in the surrounding crust [Pitman and Andrews, 1985; ten Brink *et al.*, 1993].
70 Hence, crustal extension of the DSB represents extension of the rheologically-stratified crust
71 without the complications of a mantle heat source.

72

73 The DSB is a long (~150 km), narrow (≤ 15 km), and deep (< 8.5 km) basin along the Dead Sea
74 continental transform (DST). Interpretation of the gravity field over the basin [ten Brink *et al.*,
75 1993], later confirmed by seismic refraction profiles [Mechie *et al.*, 2009; ten Brink *et al.*, 2006],
76 indicates that within data resolution (2-3 km), The Moho is not deflected upward under the
77 basin. Seismic refraction profiles also show the 18-km-deep upper-to-lower crust boundary not
78 to be deflected upward or downward [Mechie *et al.*, 2009; ten Brink *et al.*, 2006]. The absence of
79 appreciable deflection at the mid-crust and Moho levels suggests that, despite its large depth,
80 basin deformation and crustal extension are confined to the upper crust.

81

82 The DST is a strike-slip fault system (Inset in Figure 1), which currently accommodates 5 ± 1.5
83 mm/yr of left-lateral motion between the Arabian and African tectonic plates [Le Beon *et al.*,
84 2008]. A total offset of 105-110 km has accumulated along the plate boundary since the middle
85 Miocene (~17-18 Ma) [Freund *et al.*, 1970; Quennell, 1958]. The Dead Sea Basin has been
86 accumulating sediments since the formation of the plate boundary (e.g., [Calvo and Bartov,
87 2001] and continues to subside at present as evidenced by its low surface elevation (422 m
88 below sea level).

89

90 In this paper we analyze the structure and subsidence rate of the DSB to further constrain models
91 of crustal extension in cold continental crust. The paper combines the results of 2-D ray tracing
92 models of seismic refraction data, with 3-D seismic tomography of explosions, mining shots and
93 earthquakes, and 2.5-D gravity modeling in the vicinity of the Dead Sea Basin to better constrain
94 the 3-D structure of the basin and its surrounding. Simple back-stripping analysis of the basin fill
95 helps elucidate the recent change in subsidence rate. The 3-D structure of the basin and its
96 varying subsidence rate with time are discussed in the context of ductile shear bands that might
97 develop in the middle crust. Ductile shear bands might develop as feldspar undergoes retrograde
98 metamorphism to white mica in the presence of aqueous fluids.

99

100 **2 Data analysis**

101 **2.1 Wide Angle reflection and refraction**

102 Seismic data were collected during a multinational seismic refraction experiment on October 21-
103 22, 2004 [ten Brink *et al.*, 2006]. 753 miniature seismic recorders (RefTek 125, nicknamed
104 Texans) were deployed along a 280-km-long North-South profile along the transform valley and
105 a 250-km-long East-West profile across the deep part of the basin a few km north of Amazyahu
106 Fault (Figure 1). The Texans were attached to a single vertical 4.5 Hz geophone, and were
107 placed at intervals of 0.65 to 0.75 km along the profiles. Nine controlled explosions, eight of
108 1000 kg dynamite each and one of 3000 kg (Table 1), were detonated at the bottom of 25-40-m
109 deep boreholes along the receiver lines. Two additional explosions, 750-kg dynamite each,
110 (Table 1; Figure 1) were suspended at a depth of 50 m within the waters of the Dead Sea.

111

112 Prior to analysis the seismic records from all the receivers were filtered with an Ormsby
113 bandpass filter with corner frequencies at 1-2 and 10-20 Hz. The records were arranged as
114 common-shot gathers and plotted in reduced travel-time format according to their shot-receiver
115 offset (Figure A1). Phase arrivals, corresponding to refractions and prominent reflections were
116 picked. The picking error is estimated to be +/- 100 ms. Shot and receiver locations were
117 projected onto a best-fit straight line for each of the respective north-south and east-west profiles
118 to allow 2-D analysis. A forward and inverse ray tracing routine [Zelt and Smith, 1992] was
119 used to model interactively [Song and ten Brink, 2004] the 5853 phase arrivals for the E-W line

120 (Figure 2) and the 2532 phase arrivals for the N-S line, and to generate a 2-D velocity model
121 along each profile. Modeling results of the east-west line were published by *ten Brink et al.*
122 [2006]

123

124 The structure along the E-W profile is relatively 2-D, and reciprocal travel-time arrivals can be
125 identified to large shot-receiver offsets. Therefore, crustal structure along the E-W profile could
126 be modeled down to the Moho (Figure 3). As detailed in *ten Brink et al.* [2006], structures with
127 amplitudes of less than 2.5 km in the sampled Moho or the edges of the profile are not
128 resolvable. Modeling the North-South line as a 2-D structure was difficult in the area of the
129 Dead Sea Basin between shots 4 and 6, because the shot-receiver geometry does not provide
130 reciprocity due to the location of the shots within the lake and many of the receivers along its
131 eastern shore (Figure A2). The regions between shots 1 to 4 and shots 6 to 7 are modeled to an
132 approximate depth of 15 km. Deeper arrivals could not be modeled along the N-S profile
133 because the basin is narrow and ray paths probably run partially or completely within the
134 surrounding crust.

135

136 **2.2 Travel-time tomography**

137 In addition to the controlled explosions, the seismometers also recorded ten mining explosions
138 and one shallow (~15 km) local earthquake (Figure 1, Table 1) during multiple recording
139 windows of 20 minutes during October 21-22, 2004. First arrivals for all sources were picked in
140 unreduced time format because the locations of mining explosions were initially unknown
141 (Figure 4, Figure A3). A few first-arrival data, recorded by seismometers of the Geophysical
142 Institute of Israel seismic network were also picked. The seismic records from the Texans were
143 filtered as before. For consistency, the explosion data from the seismic experiment was also re-
144 picked in this manner. A total of 12,961 arrivals were picked for the tomography study; 6449
145 arrivals from the explosion shot data and 6512 arrivals from the other events. Data generated by
146 the controlled explosions were assigned a picking error of +/- 250 ms and other data (mine
147 explosion or earthquakes) were assigned a picking error of +/- 300 ms. Events not listed on the
148 Israeli earthquake catalogue were identified by seismic arrivals from our receivers in the Lisan
149 Peninsula in the Dead Sea Basin. Receivers located in the Lisan Peninsula consistently detected

150 clear first arrivals from very small events, even when the rest of our deployed receivers detected
151 very weak or no arrivals. Arrivals detected but not related to the experiment shot data were
152 preliminarily located using HypoInverse 2000 [Klein, 2002] with a simple 1-D velocity model
153 [Al-Tarazi *et al.*, 2006]. Since most of the extra events were assumed to be from quarry
154 explosions, a general new location was identified using imagery in Google Earth© and known
155 locations of quarries [Abu-Ajamieh *et al.*, 1988] in the vicinity of the initial location provided by
156 HypoInverse. In most cases the new location at an established quarry was easily found due to
157 the proximity of the preliminary location and the quarry. An approximate location error of +/- 2
158 km was assigned, which translated to change in RMS of ~0.1 s in the HypoInverse program.
159 However, the tomographic coverage is mainly the result of the sparse shot spacing and the
160 concentration of hundreds of receivers along two lines instead of being evenly distributed in
161 space (Figure 5a, Figure A4).

162

163 We used the 3-D first arrival regularized inversion method of [Zelt and Barton, 1998] that relies
164 on a linearized iterative approach to search for the simplest velocity model that will fit the
165 observed first arrivals within the accuracy of the picked error. The velocity model and ray paths
166 are both updated during each iteration with the goal of minimizing the normalized misfit χ^2
167 while keeping the velocity model smooth. Weight parameters in the inversion were varied with
168 depth with the least weight in the near-surface part of the model and increasing weight with
169 depth. An accepted final model has a low χ^2 value and RMS values between 600 – 500 ms.
170 Below χ^2 values of 4, successive iterations of the inversion do not show significant improvement
171 in RMS and the small scale variability of the velocity model increases.

172

173 The velocity model volume consisted of 351x401x56 nodes in the x, y and z directions with one
174 km spacing for a total of 140,807 nodes. Locations of events and stations were transformed
175 from latitude and longitude locations into UTM coordinates. These UTM coordinates were then
176 translated into model x, y, and z locations in units of kilometers. We used a reference point of
177 30.9860°N 35.3633°E (UTM coordinates 36R, 725678.1907, 3430447.4068) as the center point
178 of the model (x=175, y=200) and model limits of x= 0, 350, y= 0, 400, and z=-5, 50 km. A 2
179 minutes (3.25 km) interval topography grid was re-sampled and transformed into a 1 km interval

180 topography grid. This surface grid cuts into the background velocity volume to restrict ray path
181 propagations to only below the topography.

182

183 As discussed in *Zelt and Barton [1998]*, the inversion grid used to calculate the slowness of the
184 ray paths can have a larger grid size than that of the velocity model. To calculate the final
185 velocity model we started with a large inversion cell size (25 km x 25 km x 5 km) and gradually
186 reduced the size (minimum of 10 km x 10 km x 1 km; [Table 2](#)). With a large grid size,
187 smoothed general velocity trends can be approximated and found quickly. Reduction in
188 inversion grid size with each iteration step was used to fine-tune the absolute velocities in the
189 model [*Haberland et al., 2007*] and improve model fit ([Table 2](#)). Resolution tests of the model
190 are discussed in the appendix.

191

192 Starting with a laterally homogenous velocity model (after [*Al-Tarazi et al., 2006*]), and the
193 largest grid size, the major features of the velocity model can already be identified such as the
194 low velocity regions of the DSB and the Timna-Gharandal region. Differences in crustal
195 velocity with depth appear across the DST particularly along the E-W profile. Several other
196 starting models with velocity variations between the two sides of the transform valley were also
197 tested. Although the goodness of fit of the starting homogenous model is slightly worse than the
198 starting models with lateral variations across the transform valley, the final model is as good or
199 better than the heterogeneous starting models ([Table A1](#)). All final models regardless of the
200 starting model consistently show low and high velocities in the same areas and depths.

201

202 Plots of ray coverage ([Figure 5a, Figure A4](#)) help identify those parts of the model, which are
203 well resolved. Ray coverage is determined by the geometry of the receivers and sound sources.
204 The plots are binned at source-receiver intervals of 20 km. Using a basic rule of thumb of one
205 quarter of the source-receiver distance as the approximate depth of the turning point of a ray
206 path, we note that the top 5 km of the model is well covered along the receiver lines. Model
207 depth of 5-20 km is sampled by distributed ray coverage between the two receiver lines, and the
208 coverage of model depths >20 km is sparse.

209

210 Checkerboard tests (see supplementary material) show that only large-scale features in the
211 velocity model can be resolved (Figure 5b) due to the geometry of the shot and receivers. In
212 addition to the areas along the receiver lines in the model, the resolution of the checkerboard is
213 best at the top 2-5 km of the model, where velocity contrasts in the final model are large ($\pm 15\%$)
214 and it decreases with depth, where the velocity contrast is smaller (9-7%). Low velocity areas
215 are difficult to resolve in general in tomography of first-arrival travel time, due to the tendency
216 of the first arrivals to travel through the faster regions of the medium. The resolution of the
217 model seems to be robust enough in the upper 12 km of the model, which is the model region
218 needed to determine the general shape of the Dead Sea basin.

219

220 **2.3 Gravity:**

221 Gravity profiles were extracted from the combined database of gravity measurements of Israel
222 and Jordan [ten Brink *et al.*, 1999]. The two profiles were sampled at 1 km spacing along the E-
223 W and N-S profiles. Free-air gravity data was modeled with GM-SYS™ software to derive
224 density models along the two profiles (Figures 6a, 6b, and 7). Two different strategies were
225 used in each profile. To test the velocity model along the east-west profile, we converted the *P*
226 wave velocity model of ten Brink *et al.* [2006] to a density model using *P* wave velocity to
227 density relationship [Brocher, 2005] and compared the calculated gravity from this model to the
228 observed gravity profile (Figure 6a top). The calculated gravity shows a good fit to the observed
229 gravity profile in the middle section but not at the edges of the profile, possibly because the
230 velocity model is not as well constrained at the western edge of the model, and out-of-plane
231 density effects in Al-Jafir Basin dominate the eastern edge of the model.

232

233 Results from extensive geophysical work in the transform valley and the surrounding highlands
234 were used to build a density model along the north-south profile (Figure 6b, 7). This work
235 includes general crustal studies of the Middle East for depths to the crystalline basement and
236 upper sedimentary layers [Rybakov and Segev, 2004; Segev *et al.*, 2006], gravity and airborne
237 magnetic studies [ten Brink *et al.*, 1999; ten Brink *et al.*, 2007], density-depth profiles from well
238 log data [Rybakov *et al.*, 1999], sediment thickness beneath the western and eastern and western
239 highlands from boreholes [Abu Saad and Andrews, 1993; Garfunkel and Derin, 1984; Gilboa *et*

240 *al.*, 1993], and basin geometry from seismic reflection studies [*Al-Zoubi and ten Brink*, 2001; *Al-*
241 *Zoubi and ten Brink*, 2002; *Al-Zoubi et al.*, 2007; *Ginzburg et al.*, 2007; *Lazar et al.*, 2006].
242 Because of the lack of reliable crustal velocities along the N-S line, we used the velocity-derived
243 crustal densities beneath and outside the basin along the E-W (**Figure 6a**) for the crust beneath
244 the basin and outside the basin along the N-S profile. Unlike the E-W profile, the N-S profile
245 uses the 2 1/2 dimensional modeling to account for gravitational attraction of the rocks outside
246 the narrow basins and for other potential out-of-plane bodies that may contribute to the total
247 gravity profile. The basin width is loosely modeled from the observed surface expression and at
248 the deeper part of the basin it is inferred to narrow with depth following seismic reflection
249 profiles [*Al-Zoubi and ten Brink*, 2001; *Kashai and Croker*, 1987; *ten Brink and Ben-Avraham*,
250 1989]. The gravity model along this profile is used to augment our interpretation of the structure
251 of the basin.

252

253 **3. Interpretation:**

254 **3.1 Shape of the Basin**

255 Previous studies were able to map the depth of the Dead Sea basin fill in several locations. The
256 most direct evidence is the Sedom Deep-1 borehole (**Figure 6a**), which reached a depth of 6445
257 m below the surface (6830 m b.s.l), and sampled the entire basin fill of continental and lacustrine
258 mid-Miocene-to-present sediments, including a 900 m thick layer of Pliocene salt [*Gardosh et*
259 *al.*, 1997]. Identification of the base of the basin fill on seismic reflection profiles is more
260 difficult. Continental and lacustrine sediments of the Hazeva Group fill the bottom of the Dead
261 Sea basin. From geological studies the lower two formations of the Hazeva Group with a
262 maximum thickness of 200 m, were deposited before the Dead Sea Transform and the Dead Sea
263 basin started their activity [*Calvo and Bartov*, 2001]. Hence, the uncertainty in locating the base
264 of basin fill is ~200 m. South of Amazyahu Fault, *Al-Zoubi and ten Brink* [2002] identified the
265 base of the basin fill in a seismic reflection line, as dipping northward for 35 km from the
266 southern end of the basin to a depth of ~5 km (**Figure 6b**). Pre-stack depth migration of seismic
267 reflection profiles between Amazyahu fault and the Lisan Peninsula (**Figure 6b**) maps the base of
268 the basin at a depth of ~7 km [*Ginzburg et al.*, 2007] with an estimated uncertainty of ± 200 m
269 (M. Reshef, pers. Comm., 2008). The frequency of micro-earthquakes in the central basin

270 (between km 150-200 in [Figure 6b](#)) increases five fold below a depth of 7-8 [Braeuer et al.,
271 submitted], and we interpret this depth to mark the boundary between semi-consolidated basin
272 fill and the consolidated pre-basin Paleozoic to Early Cenozoic sediments. Our E-W seismic
273 refraction profile, which crosses the basin a few km north of Amazyahu fault, placed the base of
274 the basin at 6.6 km depth b.s.l., ([Figure 6a](#); [ten Brink et al., 2006]). Using poor-quality seismic
275 reflection data beneath the Lisan Peninsula, *Al-Zoubi and ten Brink* [2001] identified the base of
276 basin fill under the Lisan Peninsula at ~8 km and suggested that most of the fill there consists of
277 salt. *Mechie et al.* [2009] placed the base of basin fill under the Lisan Peninsula at 8.5 km
278 ([Figure 6b](#)). Only one refraction study was previously conducted in the northern part of the basin
279 [*Ginzburg and Ben-Avraham*, 1997]. It modeled an interface with velocity contrast of 4.8 to 6
280 km/s dipping from 6 km depth at the northern edge of the lake to 8 km at the Lisan peninsula
281 ([Figure 6b](#)). This interface was interpreted, however, as the bottom of the pre-basin sediments
282 below the basin fill, not the base of the basin fill itself. The base of basin fill in seismic reflection
283 data north of the lake is poorly defined [*Al-Zoubi et al.*, 2007; *Lazar et al.*, 2006; *Shamir et al.*,
284 2005] probably because of the narrow width of the basin. *Lazar et al.* [2006] proposed a
285 transverse fault (Kalia fault) buried under young sediments located about 15 km south of the
286 northern shore of the lake, which coincides with the epicenter of the M 5.1 2004 earthquake. We
287 use the depth constraints from the aforementioned seismic reflection and refraction studies
288 (except for that of *Ginzburg and Ben-Avraham* [1997]) in the gravity models ([Figures 6a and 6b](#))
289 and densities from the down-hole density profile of Sedom Deep-1 borehole [*Rybakov et al.*,
290 1999].

291

292 A sediment velocity gradient of 2.4 - 4.9 km/s is derived from ray tracing along the E-W line
293 ([*ten Brink et al.*, 2006]; [Figure 6a](#)), and is comparable with sonic log velocity gradient from
294 Sedom Deep-1 borehole (Inset in [Figure 6a](#)). It increases from 4.9 km/s to 5.3 km/s at the base of
295 the fill. *Mechie et al.* [2009] identified a uniformly high basin fill velocity of 4 km/s at the
296 surface increasing to 4.8 km/s at the base, which probably reflects the existence of salt in most of
297 the depth section under the Lisan Peninsula. Sediment velocity within the basin in our
298 tomographic model is higher (4.2-5.4 km/s below ~ 1 km depth, [Figure 6b](#)) than in the sonic logs
299 and the E-W ray-tracing model but is lower than in the ray-tracing model under the adjacent

300 highlands (Figures 6 and 8). The coarse resolution of the tomographic model and the uneven
301 distribution of shots and receivers tend to average the velocity across the sharp lateral boundary
302 between the slow velocities within the basin and the high velocities in the surrounding regions
303 (Figure 6a). We chose the 5.4 km/s velocity contour as the base of basin-fill in the tomographic
304 model because it fits well with depth determinations from the borehole, seismic reflection
305 profiles, and the 2-D ray-tracing model along the E-W profile. Using the 5.4 km/s contour in the
306 tomography model as the base of the basin fill, we make a general map of the shape of the basin
307 (Figure 8a). The deepest part of the basin is located under the Lisan Peninsula at a depth >8 km.
308 The basin is asymmetric along axis, as already noted in gravity modeling [ten Brink et al., 1993],
309 extending 50-60 km to the north and 80-100 km to the south.

310

311 The northern part of the basin, which is located under the lake, continues to be unusually deep
312 (>6 km) in the tomographic results (Figure 6b, 8a), but shallows rapidly at or north of the
313 northern shore of the lake. Gravity modeling suggests a more gradual thinning toward the
314 northern end of the basin (Figure 6b). In an attempt to reconcile the gravity model in the
315 northern basin with the tomographic results, we increased the basin-fill density there by placing
316 a 1-km thick dense layer (2650 kg/m³) within the basin fill. This dense layer may represent
317 basalt flows extending from Zarqa' Ma'in on the eastern shore of the lake. However, even with
318 the increased density of the basin fill, the modeled basin floor from gravity at the north end of
319 the basin cannot resemble that from the tomography. On the other hand, tomographic models
320 tend to focus lower velocities beneath the sparse explosions to improve fit to the data, and the
321 low-velocity under shot 6 (km 235 in Figure 6b) is therefore interpreted as an artifact.

322

323 A 2-D ray-tracing model, which uses reciprocal phases between Shots #6 and #7 north of the
324 Dead Sea, indicates that basin thickness decreases gradually for 28 km north of the lake and then
325 decreases rapidly in the vicinity of Ghor Katar (Figure 9a). A small exposure of older basin fill
326 rocks (Pleistocene Samra Formation) and a young volcanic outcrop are located near Ghor Katar
327 [Begin, 1975; Bender, 1974]. This exposure is coincident with a positive peak in the gradually
328 increasing Bouguer [ten Brink et al., 1999] and free-air (Figure 6b) gravity fields.

329

330 To the south, the tomography results and gravity model show that the basin remains relatively
331 deep (6-7 km) until Amazyahu Fault [Figure 6b, Al-Zoubi and ten Brink, 2001; Ginzburg et al.,
332 2007]. The basin floor rises to a depth <4 km along the Amazyahu normal fault [Ginzburg et al.,
333 2007], but is deeper again south of Amazyahu Fault (4-5 km, [Gardosh et al., 1997; Ginzburg et
334 al., 2007], Figure 6b). The basin shallows southward gradually and disappears about 50 km
335 south of Amazyahu Fault [Al-Zoubi and ten Brink, 2002, Figure 7].

336

337 Basement reaches close to the surface south of the DSB as reflected in the high seismic
338 velocities close to the surface (Figure 6b, Figure 9b). This area is also up to 200 m above sea
339 level. Two small basins were identified at the southern end of our study area in previous gravity
340 [ten Brink et al., 1998], seismic [Frieslander, 2000], and aeromagnetic studies [ten Brink et al.,
341 2007]. The Gharandal basin immediately south of the basement high of the central Arava valley
342 is approximately 2 km wide, 17 km long, and no more than 500 m deep. Its size is too small to
343 be detected by the tomography method but it shows in the 2-D ray-tracing model as a region of
344 slow seismic velocities (2.4 km/s) near the surface (Figure 9b). Timna basin at the southern end
345 of our model is approximately 6 km wide, 30 km long and 1-1.5 km deep [ten Brink et al.,
346 1999]. Due to its larger size, the Timna basin is sampled in the tomography and the wide-angle
347 with seismic velocity of 3.4 km/s, but because it is located at the edge of the seismic model, the
348 shape and depth and width of this basin are smeared (Figure 6b, Figure 9b). The gravity profile
349 shows a relatively negative anomaly over the Timna basin (Figures 6b, 8).

350

351 **3.2 Thickness of older sediments**

352 The region surrounding the DST in Israel and Jordan is covered by sedimentary rocks of variable
353 thickness and composition ranging in age from the latest Pre-Cambrian to the Eocene [Garfunkel
354 and Derin, 1984]. Pre-Permian Paleozoic sandstones increase in thickness to the south and east
355 away from the Levant Triassic-Jurassic passive continental margin, whereas Mesozoic and
356 Cenozoic sedimentary thickness increases to the north and east [Bender, 1974; Garfunkel and
357 Derin, 1984]. Limestone, dolomite, and chalk were deposited on the ancient continental shelf
358 and fluvial sediments consisting mainly of sandstone were deposited landward of the shelf
359 [Garfunkel and Derin, 1984]. The ancient coastline, which was the boundary between the two

360 lithological domains, changes its orientation from N-S to E-W at about the latitude of the DSB.
361 As a result the DST south of the DSB is underlain by thin mostly sandstone or is devoid of
362 sediments, and the DST north of the DSB is underlain mostly by much thicker carbonate rocks
363 [Garfunkel and Derin, 1984; Andrews, 1991, 1992a, 1992b; Segev et al., 2006]. Specifically, the
364 total thickness of the older sedimentary section on the western flank of the DST increases from
365 <1 km at the southern end of our study area to > 6 km at the northern end [Garfunkel and Derin,
366 1984; Segev et al., 2006]. However, the exact thickness variations and the location of the
367 lithological boundary beneath the DSB itself are unknown.

368

369 Wide-angle seismic reflection profiles across the basin place the contact between the older
370 sediments and the underlying crystalline basement at P wave velocity of 5.9 km/s, and at a depth
371 of 10-11 km north of Amazyahu Fault (Figure 6a, [ten Brink et al., 2006]) and under the Lisan
372 Peninsula [Mechie et al., 2009]. The tomographic inversion shows an increased velocity gradient
373 at 5.8 km/s, which we interpret to be the top of the crystalline basement. The depth to the 5.8
374 km/s contour varies from 12 km under the Lisan Peninsula and the southern part of the lake to 7
375 km under the Amazyahu Fault and 9-10 km under the northern end of the lake (Figure 8b). The
376 difference between the depth of basin fill (Figure 8a) and the depth to the crystalline basement
377 (Figure 8b) represents the thickness of the older pre-basin sediments. The older sediments
378 increase in thickness from 3 km in the southern half of the basin to 4 km under the Lisan
379 peninsula and under the lake to 5-6 km under the Jordan valley north of the Dead Sea. However,
380 the lateral resolution of this change is probably no better than 20-25 km as evident by the
381 extension of basin contours beyond the width of the basin (Figure 8b).

382

383 The 2 1/2-D gravity model along the axis of the DST is compatible with the thickness variations
384 in the tomography model (Figure 7b). The model accounts for variations in the width of the
385 basin along the axis of the DST, and known changes in the thickness and lithology of the
386 sediment cover immediately west and east of the DST valley. The gravity model under the DST
387 assumes that the south-to-north variations in the thickness and lithology of the older sediment
388 layer is similar to that under the western flank of the DST (Figure 7), implying that the general
389 plate boundary at depth is closer to the eastern side of the transform valley. The calculated

390 gravity from this model produces a good fit to the observed gravity (Figure 6b, top). Note that
391 the northward increase in thickness of the older pre-basin sedimentary layer is not manifested in
392 the gravity field. This is due to the change from mainly sandstone composition in the south,
393 which has an average density of 2550 kg/m³ to limestone and dolomite, which have an average
394 density of 2650 kg/ m³ [Rybakov et al., 1999].

395

396 **3.3 Deeper structure:**

397 E-W profiles from ray tracing of wide-angle reflection data show an anomalously low seismic
398 velocity in the upper crust below the DSB (6.1-6.5 km/s, [ten Brink et al., 2006], Figure 6a; 5.9-
399 6.4 km/s, [Mechie et al., 2009]) relative to upper crustal velocity in the surrounding area (6.3-6.5
400 km/s). Whether the lower P-wave velocity in the upper crust is associated with a lower density
401 cannot be resolved. Models with lower density following empirical velocity-density
402 relationships [Brocher et al., 2005], and models without a density anomaly in the upper crust fit
403 both the N-S and E-W gravity profiles equally well. Because we do not know of processes
404 capable of reducing upper crust density under the basin, we do not assign anomalous density to
405 the region of anomalous velocity.

406

407 The lower crust velocity under the DSB in the E-W wide-angle seismic profiles (6.8-7 km/s;
408 Figure 6a) is similar to that to the east and west, giving no indication of lower crustal extension,
409 contrary to predictions from thermo-mechanical models with layered crustal rheology [Petrunin
410 and Sobolev, 2006, 2008). The upper-to-lower crustal boundary under the basin at depth of 18
411 [ten Brink et al., 2006] to 20 km [Mechie et al., 2009] is not deflected upward as predicted by
412 analog models of brittle upper crust and ductile lower crust [Wu et al., 2009]. Micro-seismic
413 activity in the region between Amazyahu Fault and the Lisan decreases five-fold below a depth
414 of 17 km ([Braeuer et al., submitted], Figure 6b). The Moho is at depth of 30-31 [ten Brink et
415 al., 2006] to 32.5 km [Mechie et al., 2009]. The wide-angle seismic data ([Ginzburg et al., 1979;
416 ten Brink et al., 2006], Figure 6a) and the gravity model (Figure 7a) suggest that crustal
417 thickness decreases across the passive continental margin toward the Eastern Mediterranean Sea.

418

419 **4. Basin subsidence**

420 Changes in subsidence rate with time provide an important constraint on the formation process
 421 of pull-apart basins. Subsidence rate is commonly estimated using the backstripping method
 422 [Steckler and Watts, 1978], which successively de-compacts the present-day stratigraphic
 423 thickness of layers within the basin to their thickness at the time of deposition. Corrections for
 424 water depth at the time of deposition and for variations in sea level from present sea level must
 425 also be made. Thus, the Airy compensated tectonic subsidence, Y , is

426 (1)

$$427 \quad Y = W_d + S^* \left[\frac{(\rho_m - \bar{\rho}_s)}{(\rho_m - \rho_w)} \right] - \Delta_{sl} \frac{\rho_m}{(\rho_m - \rho_w)}$$

428

429 Where W_d is the water depth, S^* is the de-compacted sediment thickness, Δ_{sl} is the height of mean
 430 sea level with respect to a reference surface and ρ is the density for the mantle (m), sediment
 431 layer (s) and water (w) respectively. For the Dead Sea basin, which was disconnected from the
 432 world oceans for much of its history and contains fluvial and lacustrine sediments, sea level and
 433 water depth are set to zero. The backstripping equation is further simplified by ignoring isostatic
 434 compensation. Isostatic compensation can be ignored because the basin is narrow (10-15 km)
 435 relative to typical flexural wavelengths of the lithosphere [ten Brink *et al.*, 1993]. Hence, $Y = S^*$.
 436 The de-compacted sediment thickness is,

437 (2)

$$S^* = \left(\frac{1 - \varphi_{si}}{1 - \varphi_{si}^*} \right) S$$

439 Where, S the layer thickness after compaction for a given depth, φ_{si} is the layer porosity after it
 440 underwent compaction for a given rock type at a specific depth and φ_{si}^* is the initial layer
 441 porosity before compaction. Variations of porosity with depth of burial can be complex, but are
 442 often simplified by an exponential decrease with depth

443 (3)

$$\varphi_{si} = \varphi_{si}^* e^{-cz}$$

444 Where φ_{si} is the porosity for a formation at a specified depth, φ_{si}^* the initial porosity at the
 445 surface, c is the lithology dependent coefficient rate of exponential decrease in porosity with
 446 depth and z is a given depth [e.g., Hölzel *et al.*, 2008]. Formation porosities are calculated using
 447 values for φ_{si}^* and c is given by Hölzel *et al.* [2008 (Table 3)]

448

449 The Sedom Deep-1 well is located close to the deepest part of the basin (Figure 1) and is
450 therefore considered to be a representative sample for the total basin subsidence history. We
451 used the approximate percent compositions of marls and sandy marls in the Sedom Deep-1 well
452 log to calculate φ and c for the different layers of basin fill (see Table 3). The well section was
453 divided based on the interpretation of the gamma-ray log to six major depositional sections
454 [Larsen *et al.*, 2002]: Hazeva Group (17-6 Ma; 6448 – 4700 m depth), Sedom salt (6 - 3 Ma;
455 4700 – 3750 m depth), Melech Sedom (3 – 1 Ma; 3750 – 2950 m depth), Amora 1 Formation (1
456 – 0.7 Ma; 2950 – 2100 m depth), Amora 2 Formation (0.7 – 0.3 Ma; 2100 – 1400 m depth), and
457 Lisan-Samra Formation (0.3 Ma – present; 1400 – 0 m depth). The lithological descriptions are
458 based on the interpretations of Larsen *et al.* [2002], Gardosh *et al.* [1997], Calvo and Bartov
459 [2001], Horowitz [1987], Bartov *et al.*, [2002], and Bartov *et al.*, [2007].

460

461 The Hazeva Group, which outcrops at the southern end of the DSB, consists of 5 geologic
462 formations, with the two lowest formations (Efe and Gidron) being older than the ~17 Ma age
463 of the DST (as old as 20 Ma [Calvo and Bartov, 2001], or 23.8 Ma [Horowitz, 1987]). These two
464 formations are <200 m thick and their inclusion in the subsidence calculation introduces only a
465 small error to the subsidence rate. On the other hand, it is not clear if the Sedom Deep-1 well
466 reached the bottom of Hazeva Formation [Gardosh *et al.*, 1997; Calvo and Bartov, 2001]. The
467 Sedom Salt Formation in this well consists of 950 m of halite with a mix of anhydrite and
468 gypsum, but the presence of large salt diapirs within the DSB suggests salt migration with time.
469 Horowitz [1987] estimated the original thickness of salt layer between 1000-1200 m, and
470 Garfunkel [1997] suggested it to be 2000 m. The Sedom Salt formation is calculated using two
471 end member scenarios: one where only 950 m were deposited during the Pliocene and the
472 other, where 2000 m of salt were deposited, but the layer thickness has since been decreasing
473 linearly with time at a rate to the current observed thickness of 950 m.

474

475 The Melech Sedom unit of the Amora Formation consists of 800 m of mostly of quartz
476 sandstones deposited in the late Pliocene-early Pleistocene [Horowitz, 1987]. The remaining
477 Pleistocene-age Amora Formation is divided into two sections. The Amora 1 section is an 850-
478 m-thick fining upward deposition sequence with dominant sands interlaced with shales and the

479 Amora 2 section comprises of 600-m-thick mix of shale and sands overlain by 100 m of mostly
480 shales [*Gardosh et al.*, 1997; *Larsen et al.*, 2002]. The Lisan-Samra Formation consists of a
481 1400-m-thick sequence of shaley sands with clays and lake carbonates deposited from 0.70 –
482 0.150 Ma [*Begin*, 1975; *Bartov et al.*, 2002; *Bartov et al.*, 2007]. The surface at Sedom Deep-1
483 well is currently at ~380 m. Because of the lack of constraints on the rate of surface subsidence,
484 the entire 380 m were added to the most recent section.

485

486 The total tectonic subsidence of the basin ([Figure 10](#)) is close to the total thickness of sediments
487 for three reasons: (a) isostatic amplification was not considered; (b) the large time interval
488 represented by the Hazeva Group was de-compacted as a single unit; and (c) the mainly salt
489 layer of Sedom Salt Formation was not de-compacted at all. The subsidence rate appears to have
490 been fairly constant at a few hundred meters/m.y. throughout the life of the basin and has
491 accelerated by an order of magnitude about 1 m.y. ago ([Figure 10](#)). Using U-series and oxygen
492 isotope chronology for the mid-Pleistocene, *Torfstein et al.* [2009] suggested that a gypsum layer
493 at a depth of 540 m was deposited 420 ky ago. This depth-age pair implies a slightly lower
494 subsidence rate for the late Pleistocene (grey dot in [Figure 10](#)), but this rate is still an order of
495 magnitude higher than the Mio-Pliocene subsidence rate.

496

497 Subsidence rates of a few hundred m/m.y. appear to be typical to other basins along the DST.
498 $^{40}\text{Ar}/^{39}\text{Ar}$ dating of basalt layers in a 2781-m-deep well at the center of the Hula basin ([Figure 1](#))
499 gives a uniform rate of subsidence (not corrected for compaction) of 500-700 m/m.y. since 4.1
500 Ma [*Heimann and Steinitz*, 1989]. Pollen dating of a 4249-m-deep well in Kinarot basin ([Figure](#)
501 [1](#)) gives an uncorrected subsidence rate of 500 m/m.y. since 1.8 Ma and ~300 m/m.y. since
502 Middle Miocene [*Horowitz*, 1987].

503

504 In the Dead Sea basin the accelerating subsidence rate during the Pleistocene is supported by
505 geological evidence. Sedimentation during the Miocene has kept up with subsidence as indicated
506 by evidence for occasional sediment transport from east to west across the basin [*Garfunkel and*
507 *Horowitz*, 1966]. Sands within the Pliocene salt layer were derived from the underlying Hazeva
508 Group sediments, whereas sands in the Amora Formation sample the entire Phanerozoic section

509 [Sa'ar, 1985], indicating that the present topography of a basin and uplifted highlands has
510 mainly developed during the Pleistocene [ten Brink and Ben-Avraham, 1989]. The present
511 surface elevation of the lake (-422 m) also suggests that sedimentation has recently not kept up
512 with subsidence. Estimates of subsidence rate from interferometric synthetic aperture radar
513 (InSar) measurements are 0-20 mm/y, although it is difficult to separate consolidation, salt
514 movement, and hydrologic effects from tectonic subsidence [Baer *et al.*, 2002].

515

516 **5. Discussion – the role of fluids in basin subsidence**

517 Several observations about structure and temporal evolution of the DSB provide important
518 constraints on its mechanical development. 1. The lower crust below 18 km does not appear to
519 be affected by basin development, despite the great depth of the basin (≤ 8.5 km). 2. Upper
520 crustal P-wave velocity is anomalously low in a narrow (10-15 km) zone beneath the basin. 3.
521 Subsidence rate has accelerated by an order of magnitude during the past 1 m.y.

522

523 A decrease in upper crust *P* wave velocity under the basin is interpreted to be the result of higher
524 than typical pore fluid pressure in that layer [e.g., Stern *et al.*, 2001]. The magnitude of the
525 decrease depends on pore geometry; the decrease is small if the pores are round but is significant
526 if pores are thin and long [Marquis and Hyndman, 1992]. It is less likely that the reduction in
527 wave speed is due to dry fractures, because dry fractures will likely shut with depth [Mooney
528 and Ginzburg, 1986]. The fluid source to the middle crust could be fluids drawn from the
529 surrounding crust by the large negative vertical stress (≤ 45 MPa) under the basin due to its
530 lighter overburden relative to the surrounding areas (Figure 11a), and/or by dehydration of the
531 upper mantle and migration up deep shear zones. Kennedy *et al.* [1997] used $^3\text{He}/^4\text{He}$ ratio in
532 wells, springs, and seeps along the San Andreas Fault to suggest that mantle fluids pass through
533 the ductile crust into the brittle fault zone. The helium ratio indicates that between 1%-50% of
534 the surface fluids may originate in the mantle. Kennedy *et al.* [2007] documented a positive
535 regional correlation between $^3\text{He}/^4\text{He}$ ratios in surface fluids in the western U.S. and the rate of
536 crustal extension and shear strain. Friedman *et al.* [1999] discussed possible evidence for mantle
537 or lower crust fluids in groundwater along the DST, although a thorough analysis has not been
538 done.

539

540 Retrograde metamorphic reactions of feldspar in the presence of pore fluids have been
541 documented in several shear zones in the middle continental crust [*Beach, 1980; Gueydan et al.,*
542 2003; *Janecke and Evans, 1988*]. The metamorphic reactions produce muscovite, which alters
543 the fabric and strength of the deformed rock by producing weak, highly foliated mica bands.
544 Laboratory deformation experiments of thin layers of oriented muscovite aggregate (simulated
545 shear zone) show semi-brittle behavior at low strain rates at temperatures < 700°C, but at 700°C
546 the shear strength falls rapidly with a linear-viscous characteristic [*Mariani et al., 2006*].
547 Extrapolating these results to geological strain rates (10^{-12} - 10^{-14} s⁻¹), these authors proposed a
548 rapid strength drop by viscous creep at depths of 15-18 km (assuming a temperature gradient of
549 22°C/km and an overburden rate of 27 MPa/km). Laboratory experiments of fine-grained
550 feldspar aggregate at higher pressure and temperatures show that water in isolated pores under
551 hydrostatic conditions changed during deformation to wetted grain boundaries [*Tullis et al.,*
552 1996]. A significant strength drop and an order of magnitude increase in bulk transport rate
553 through the aggregate accompanied the fluid re-distribution, and the deformation mode changed
554 from dislocation creep to diffusion creep. A similar effect was not seen in quartz.

555

556 *Bailey [1990]* proposed that aqueous fluids can percolate rapidly through the ductile lower crust,
557 but are trapped at the brittle-ductile transition within the crust because of the low permeability of
558 the brittle crust. Given the generally compressive state of stress in the continental lithosphere
559 [*Zoback, 1992*], the fluids are expected to accumulate in horizontal layers aided perhaps by
560 hydraulic fracturing. As shown by the ³He/⁴He ratio in the San Andreas Fault [*Kennedy et al.,*
561 1997], the presence of a continental transform zone under the DSB will likely aid in the transport
562 of fluids to the middle crust.

563

564 We propose that the sudden increase in subsidence rate of the DSB is the result of hydration
565 reactions causing retrograde metamorphism of feldspar to muscovite in the middle crust. This
566 alteration helped focus the extension into narrow inter-connected mid-crustal ductile shear zones
567 ([Figure 11b](#)) resulting in a significant shear strength reduction and a significant increase in
568 transport rate in that layer. An increase in subsidence rate under the basin can occur if the ductile

569 shear zones extend horizontally to the crust surrounding the basin and spread the subsidence
570 over a broader region or if the ductile shear zones connect vertically to deeper crustal levels or to
571 shallow low-angle faults.

572

573 The connection of mid-crustal shear zones to deeper or shallower levels in continental rifts is
574 expected to result in exhumation of the lower crust and/or upper mantle [e.g., *Lavier and*
575 *Manatschal*, 2006]. Because there are no observations of lower crustal exhumation and shallow
576 low-angle faults along the DST, ductile shear zones under the DSB are probably confined to the
577 middle crust and distribute the subsidence over a broader region. The clearest example of
578 distributed subsidence is the “sagging” of the basin south of the Amazyahu transverse fault
579 without significant transverse faulting ([*Al-Zoubi and ten Brink*, 2002], [Figures 1, 6b](#)). *Larsen et*
580 *al.* [2002] proposed that a southward migration of the depocenter across Amazyahu fault started
581 ~1 m.y. ago. Farther south, the basin gradually thins until it disappears about 50 km to the south.
582 Stratigraphic relationships in this part show possible onlap to the south, which is interpreted as
583 lengthening of the basin with time ([Figure 11b](#)). The average Pleistocene subsidence of the
584 southern part is at least 1.25 km [*Al-Zoubi and ten Brink*, 2002]. Other areas of subsidence are
585 more speculative: The central ~80 km of the basin is ~15 km wide, 5 km wider than the gap
586 between the strike-slip fault strands (e.g., [Figure 7](#)). The region outside the fault strands consists
587 of subsided blocks of intermediate depth along the west side [*Kashai and Crocker*, 1987; *ten*
588 *Brink and Ben-Avraham*, 1989] and in places also along the east side [*Al-Zoubi et al.*, 2002].
589 Post mid-Pleistocene subsidence is estimated to be at least 1.5 km (Amiaz borehole [*Gardosh et*
590 *al.*, 1997]). The northern 20 km of the basin, where the surrounding blocks of intermediate depth
591 almost disappear ([Figure 7](#)), could perhaps accommodate ≤ 2 km of subsidence, but its geometry
592 and subsidence history are poorly constrained. Lastly, extrapolating GPS rates of motion
593 suggests that the upper crust of the pull-apart basin probably extended by ~5 km during the past
594 1 m.y. Of the 4-km of subsidence since 1 m.y. ago, ~1 km of subsidence in the central ~80 km of
595 the basin could have been the result of partial evacuation of the Pliocene salt into diapirs
596 [*Garfunkel*, 1997], which may have started in the mid-Pleistocene [*ten Brink and Ben-Avraham*,
597 1989]. The remaining subsidence can then be balanced by the subsidence south, west, and
598 perhaps north of the deepest part of the basin, and by the predicted extension during that period.

599 Hence, we propose that the increased subsidence rate in the central deep part of the DSB is
600 accommodated by subsidence in a broader region.

601

602 The DSB may not be the only basin where rapid subsidence unrelated to a tectonic event has
603 occurred. For example, an anomalous rapid subsidence phase, accompanied by minor normal
604 faulting was documented in the North Sea around 55 Ma, when the North Atlantic mantle plume
605 reached the earth surface [*White and Latin*, 1993]. That subsidence could not be satisfactory
606 explained by tectonic or isostatic causes [*Hall and White*, 1994]. On the other hand, *White and*
607 *Latin* [1993] summarized evidence for rapid illite diagenesis and the presence of unusually warm
608 saline pore fluids in quartz fluid inclusions within the sediments during that time without
609 commenting on its origin or relationship to the subsidence. Magmas from the Iceland plume
610 have elevated water content [e.g., *Poreda et al.*, 1986]. Hence, it is possible that aqueous fluids
611 related to the mantle plume rose to the middle crust to create mid-crustal ductile shear zone
612 during a minor extension event, perhaps itself driven by the rising plume.

613

614 We propose that the rapid subsidence starting 1 m.y. ago is a culmination of slow fluid migration
615 into the middle crust and micro faulting there for many millions of years as the basin deepened
616 and the transform fault continued to be active in the same location. Aqueous fluids can be drawn
617 from the deeper crust and mantle and from the surrounding crust into the middle crust under the
618 DSB by the large negative vertical stress (≤ 45 MPa) under the basin due to its lighter
619 overburden relative to the surrounding areas ([Figure 11a](#)). A positive feedback exists during the
620 extension process, which helps concentrate fluids at the base of the quartzo-feldspatic crust as
621 the basin continues to deepen and the overburden to lighten. Micro-faulting and fracturing of the
622 crust during the millions of years of seismic activity along the DST further facilitates fluid
623 accumulation under the basin.

624

625 An alternative explanation for the 4 km of subsidence of the DSB in the past ~ 1 m.y. is that a
626 change in relative plate motions in the Eastern Mediterranean region at that time [*Schattner and*
627 *Weinberger*, 2008] has resulted in a small component of extension across the basin. However,
628 because the pole of rotation between Arabia and Africa (or the Sinai block) is close to the plate

629 boundary and is not well constrained, different solutions may produce different senses of motion
630 across the basin [*Le Beon et al.*, 2008]. Moreover, the internal stratal relationships of the shallow
631 basin fill do not show evidence for E-W extension [e.g., *Al-Zoubi et al.*, 2002; *Larsen et al.*,
632 2002]. The continued rise of the Sedom salt diapir above the surface [*Weinberger et al.*, 2006]
633 requires, in fact, the presence of a slight E-W compression, as discussed by *Al-Zoubi and ten*
634 *Brink* [2001]. The recent increase in subsidence rate does not represent thermal subsidence,
635 because the basin is narrow and any increase in thermal gradient due to mantle upwelling is
636 continuously offset by lateral heat conduction to the surrounding area [*Pitman and Andrews*,
637 1985; *ten Brink et al.*, 1993].

638

639 Another alternative explanation to the 4 km of subsidence in the past 1 m.y. is an increase of
640 mantle heat flux that has not yet reached the surface. *Moshen et al.* [2006] determined a thinner
641 than normal (70-80 km) lithosphere from receiver-function analysis and suggested that it reflects
642 late Cenozoic thinning. *Al-Damegh et al.* [2004] mapped a zone of high *Sn* attenuation along the
643 eastern side of the Dead Sea fault system. A thinner and hotter lithosphere under the DSB than is
644 expected from surface heat flow, could result in lower viscosity and the onset of lower crust
645 flow. However, the detection of earthquake hypocenters within the lower crust [*Aldersons et al.*,
646 2003; *Braeuer et al.*, submitted] argues against a hot lower crust. Micro-seismicity in the lower
647 crust can be understood however, in the context of rapidly rising fluids in the lower crust. If the
648 ascent rate is fast enough, fluids can locally create hydro-fracturing even within the ductile crust,
649 and thinning of the lithosphere could also promote the production of aqueous fluids.

650

651 **6. Conclusions**

652 Based on the information and interpretations presented above as well as other published studies,
653 we characterize the structure and evolution of the DSB as follows:

- 654 1. The basin is up to 8-8.5 km deep under the Lisan Peninsula. Previous estimates of the
655 maximum depth of the basin using gravity did not consider lower density in the upper
656 crust under the basin and hence required a thicker basin fill to explain the added negative
657 gravity anomaly.

- 658 2. The basin extends 50 km farther south of the only significant transverse normal fault, and
659 gradually shallows without significant brittle deformation. The internal stratigraphy of
660 the basin fill suggests that the basin proceeded to elongate southward with time after its
661 formation [Al-Zoubi and ten Brink, 2002].
- 662 3. The shape of the northern termination of the basin is not well determined. Gravity
663 modeling suggests gradual thinning toward the northern end of the lake (Figure 6b, 7).
664 Tomographic inversion, on the other hand, suggests that the basin continues to be 6 km
665 deep to the northern end of the lake (Figure 6b, 8) where it abruptly thins, but the spatial
666 resolution of the tomography is probably no better than 25 km. There is no clearly
667 imaged transverse fault at the northern end of the lake although one was suggested [Neev
668 and Hall, 1979; ten Brink and Ben-Avraham, 1989; Lazar et al., 2006]. A 2-D ray-
669 tracing model (Figure 9a) shows the basin depth as < 2.5 km immediately north of the
670 lake thinning to 1.5 km 50 km to the north.
- 671 4. The underlying pre-basin sedimentary layer thickens gradually under the DST from 2-3
672 km under the southern edge of the DSB to 3-4 km under the northern end of the lake and
673 5-6 km farther north. At the deepest part of the basin under the Lisan, the pre-basin
674 sediments reach a depth of ~11 km. The layer's lithology changes from predominantly
675 clastic east and south of the DSB to carbonate west and north of the DSB. The thickness
676 and lithology reflect the location of the DSB at a bend of the Triassic-Jurassic passive
677 continental margin of the Tethys Ocean.
- 678 5. The upper crust under the deep part of the basin has a lower *P* wave velocity than in the
679 surrounding regions. Within the data resolution, the lower crust below ~18 km and the
680 Moho are not affected by basin development.
- 681 6. The basin started forming during or shortly after the development of the DST ~17 Ma.
682 Subsidence rate was several hundreds m/m.y. for most of that period, similar to other
683 basins along the DST, but subsidence rate has accelerated by an order of magnitude
684 during the Pleistocene or perhaps only in the past 1 m.y.

685

686 We explain the anomalously low velocity in the upper crust under the basin, the apparent
687 sagging and extension of the basin, and the rapid subsidence in the past 1 m.y., by the influx of

688 fluids from the surrounding crust and/or the upper mantle into the middle crust, where these
689 fluids interacted with fractured feldspar to alter some of the feldspar to muscovite. The
690 generation of interconnected muscovite shear bands profoundly weakened the yield strength in
691 this part of the crust and allowed sub-horizontal viscous deformation, and a significant increase
692 in the rate of horizontal transport. These caused the basin to subside rapidly with only minor
693 attendant brittle faulting. We propose that the enigmatic rapid Tertiary subsidence of the North
694 Sea could have been generated by a similar mechanism. Thus, we propose that aqueous fluid
695 flux into a slowly extending continental crust can cause rapid basin subsidence that may be
696 erroneously interpreted as an increased rate of tectonic activity.

697

698 Several observations can possibly test the hypothesis that the recent acceleration in subsidence
699 rate is driven by the development over mid-crustal shear zones. These observations include
700 geochemical and petrologic work to examine evidence for potential influx of lower crust and
701 upper mantle aqueous fluids, identifying episodic micro-seismic activity near the base of the
702 upper crust using a semi-permanent network of seismometers around the basin, and obtaining
703 higher-resolution seismic stratigraphy south of Amazyahu Fault to determine the geometry and
704 rate of sagging. Continuous geodetic monitoring of surface subsidence south of Amazyahu Fault
705 and north of the lake may also help detect extension episodes. Finally, deeper penetrating
706 seismic reflection observations of the northern basin, and seismic tomography with more
707 regularly spaced seismic sources and receivers, will improve the constraints on the geometry of
708 the DSB.

709

710 **Acknowledgments:**

711 Fieldwork was funded by US-AID Middle Eastern Regional Cooperation Program grant M21-
712 012, with in-kind contributions by Al-Balqa' Applied University (Jordan), the Geophysical
713 Institute of Israel, and the U.S. Geological Survey. Abdallah Al-Zoubi, Yair Rotstein, and Randy
714 Keller helped coordinate the project. IRIS and the University of Texas, El Paso, kindly provided
715 seismic equipment. Steve Harder and Isam Qabbani coordinated the field deployment, and
716 Jordanian and Israeli crews, Matt Averill, Galen Kaip, and Tip Meckel provided field support.
717 We thank Moshe Reshef for discussion and information. Discussions with Tim Stern

718 substantially improved the manuscript. Tim Stern, Carolyn Ruppel, Uri Schattner, an anonymous
719 reviewer, and associate editor Gail Christeson provided helpful reviews.

945

946 **Figure captions**

947 **Figure 1.** Location of deployed seismometers (black) and explosions (red circles) detonated as
948 part of the 2004 active source experiment plotted on shaded relief topography. Red stars – other
949 mining explosions and earthquakes that were recorded during the 2-day deployment and used in
950 the tomography. Numbers correspond to source locations in Table 1. Dashed rectangle defines
951 the area of the tomographic grid. Red lines – Fault geometry simplified from *ten Brink et al.*
952 [1999]. SD-1 – Sedom Deep-1 hole. (Inset) Simplified tectonic map of the Middle East.

953

954 **Figure 2 -** Observed (in black) and calculated (in red) travel times for sources used for the
955 modeling the W-E line. See [Figure 1](#) for source location.

956

957 **Figure 3 –** (A) Ray coverage for diving waves (red) and wide-angle reflections in the model
958 (black). (B) Bottoming points for the rays in (A).

959

960 **Figure 4 -** Receiver gathers for sample sources. See Table 1 for locations. The complete data is
961 shown in [Figure A3](#) in the supplementary material. The gathers were plotted with no time
962 reduction. Receivers 1 to 409 were aligned from south to north and receivers 410 to 755 were
963 aligned from west to east. Red line – first arrival pick for tomography.

964

965 **Figure 5 –** (A) Ray-path coverage for various shot-receiver distances binned at shot-receiver
966 increments of 20 km. Additional binned increments are found in [Figure A4](#) in the supplementary
967 material. Color dots indicate midpoints for each ray path. Note the uneven coverage due to the
968 locations of all the receivers along two lines (except for a few permanent stations of the Israeli
969 seismic network), and the locations of 14 of the sources at or near these two lines. (B) Depth
970 slices in the checkerboard test. Top – Perturbations in the final velocity model by higher and
971 lower velocities in a checkerboard pattern. Bottom – recovered model. Detailed discussion of the
972 technique and additional depth slices are given in the supplementary material and [Figure A5](#).

973

974 **Figure 6.** (a) Top - Comparison between calculated and observed free-air gravity anomaly along
975 the E-W seismic profile (bottom). Density model was derived from the *P* wave velocity model
976 using velocity/density relationships of *Brocher et al.* [2005]. Misfit between calculated and
977 observed anomalies in eastern Jordan may be caused by negative anomaly from Al-Jafr basin
978 south of profile. Bottom - *P* wave velocity contours along the east-west receiver profile from a
979 2-D ray-tracing model (**Figure 1**). Red lines – selected velocity contours from the 3-D
980 tomographic model. Colored bodies – interpreted structure: Dark yellow – basin fill; Light
981 yellow – pre-basin fill sediments; Green – upper crust; Orange – lower crust. Stars – controlled
982 explosions. Vertical blue line – depth of Sedom Deep-1 (SD-1) well. Inset – Comparison of
983 basin-fill velocity along the blue line (red) with sonic-log velocity of Sedom Deep-1 well
984 (black). (b) Top – Observed Free-air anomaly along profile in bottom and calculated gravity
985 anomaly using 2.5-D density model shown in **Figure 7**. Bottom – Contours of *P* wave velocity
986 from a slice of the 3-D tomography model along the center of the Dead Sea Transform valley.
987 Thin lines - bodies in gravity model with density values (red) in 10^3 kg/m^3 . Colored bodies –
988 same as in (a) with additional bodies: light blue – salt layer; dark blue – lake water (with a
989 density of 1280 kg/m^3). Shape of Lisan salt diapir is approximate after *Al-Zoubi and ten Brink*
990 [2001]. Dashed colored lines – depth to basin floor and where available, to crystalline basement
991 from previous seismic data (Red – *Al-Zoubi and ten Brink*, 2002; purple – *Ginzburg et al.*, 2007;
992 Green – *Al-Zoubi and ten Brink*, 2001; Blue – *Ginzburg and Ben-Avraham*, 1997). Black crosses
993 – Depth to basement and lower crust in 3 perpendicular seismic refraction profiles: DESERT
994 [*Mechie et al.*, 2005], E-W line ([*ten Brink et al.*, 2006] and **Figure 6a**) and DESIRE [*Mechie et*
995 *al.*, 2009]. Dashed brown double-sided arrow bounded by brown dashed horizontal lines – Depth
996 range of most micro-earthquakes in this part of the basin [*Braeuer et al.*, submitted], A.F. –
997 Amazyahu Fault; K.F. – Kalia Fault (proposed by *Lazar et al.* [2006]).

998

999 **Figure 7.** Three slices 2.5-D N-S density model for **Figure 6b**, west of the transform valley,
1000 along of the valley and east. The main sedimentary layers along the transform valley are also
1001 outlined on the East and West profiles. Arrows indicate the total width of the density structure
1002 over the transform valley. Densities within the basin fill are shown in **Figure 6b**. See legend for
1003 pre-basin sediment density (in 10^3 kg/m^3). Crustal densities increase with depth throughout the

1004 model with values (in 10^3 kg/m^3) in white. Upper crustal densities in a 10-km-wide zone under
1005 the basin are lower than in the rest of the model by the shown amount. The 2.5-D model
1006 accounts for higher densities east and west of the narrow transform valley. It uses the available
1007 constraints from surface and subsurface geology, seismic reflection data, and tomographic
1008 analysis, as discussed in text.

1009

1010 [Figure 8](#). Depth (in km) to (a) 5.4 km/s and (b) 5.8 km/s velocity contours from the tomography
1011 model. Contours are plotted on top of a Bouguer gravity anomaly map. Red triangles – seismic
1012 receivers. Circles – location of controlled explosions. Stars – Quarry explosions. An outline of
1013 Dead Sea shoreline in 1965 and rivers are shown in white for reference. The 5.4 km/s contour is
1014 interpreted as a proxy for the basin floor and the 5.8 km/s contour as the top of crystalline
1015 basement. Bouguer anomaly map is used to qualitatively define the extent of the basin.

1016

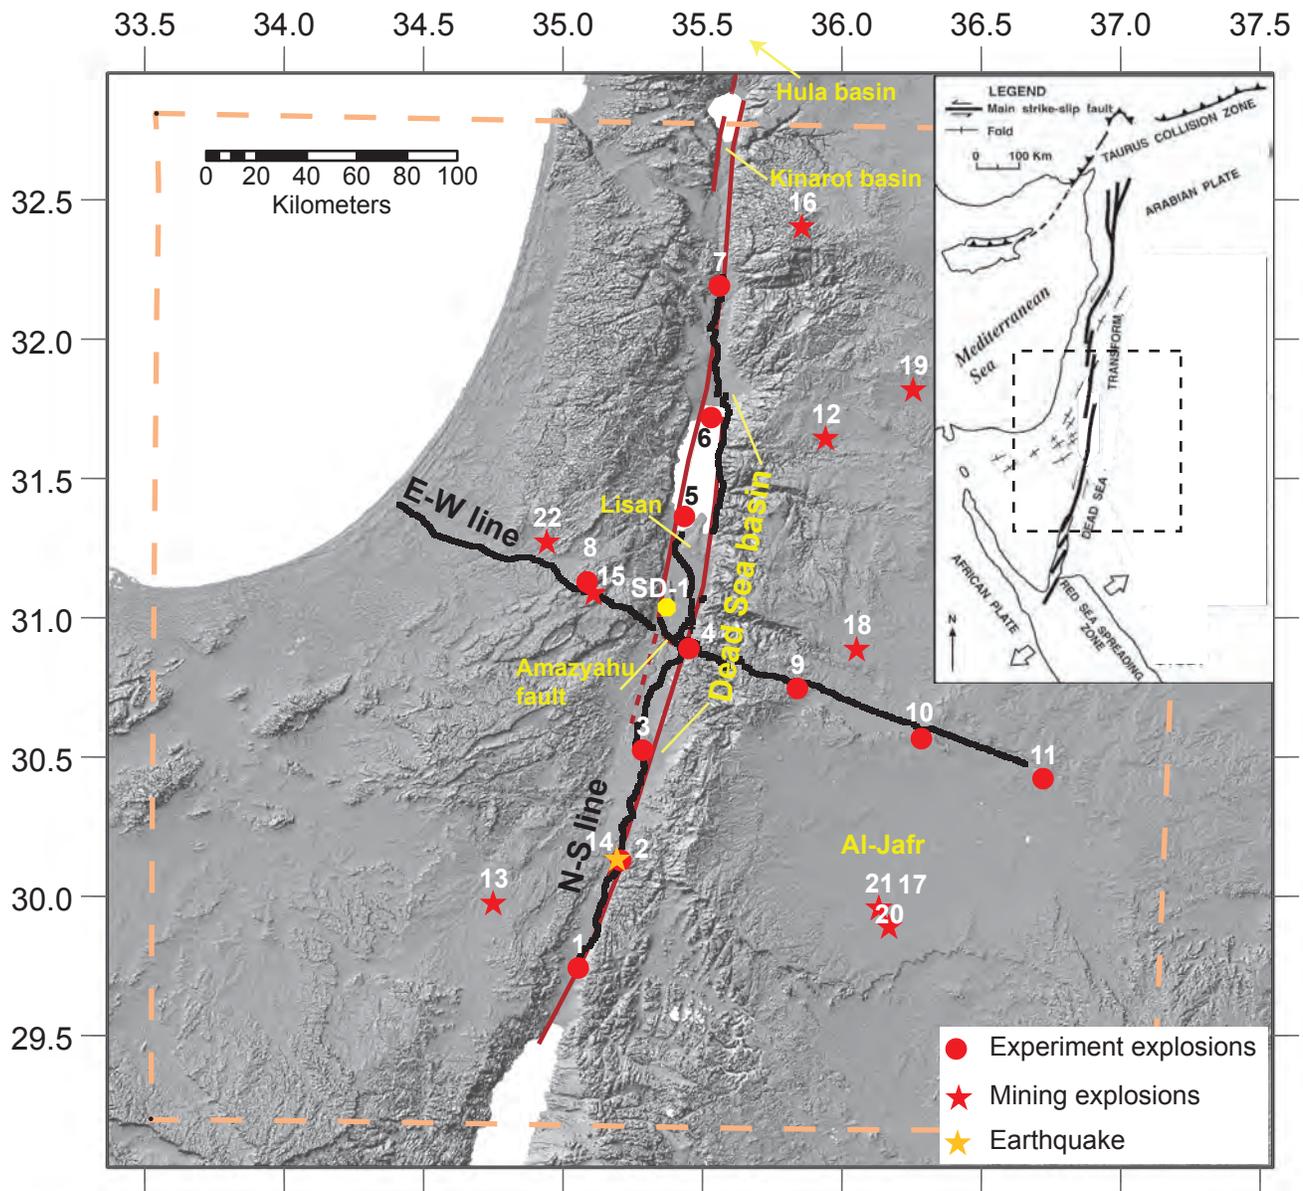

1017 [Figure 9](#). *P* wave velocity model along the transform valley (a) south of Amazyahu fault and (b)
1018 north of the lake. Colors are *P* wave velocities gridded from the 2-D ray-tracing model. Black
1019 lines are layer boundaries used in the model and do not always have geologic significance.
1020 Purple dashed lines – base of basin fill and crystalline basement from the gravity model in
1021 [Figure 6b](#). Stars – controlled explosions. High velocity around km 260 probably corresponds to
1022 the base of a basalt outcrop of Ghor Katar [*Begin, 1975; Bender, 1974*], which may also be
1023 manifested as a local peak in the gravity profile ([Figure 6b](#)). (c) location map.

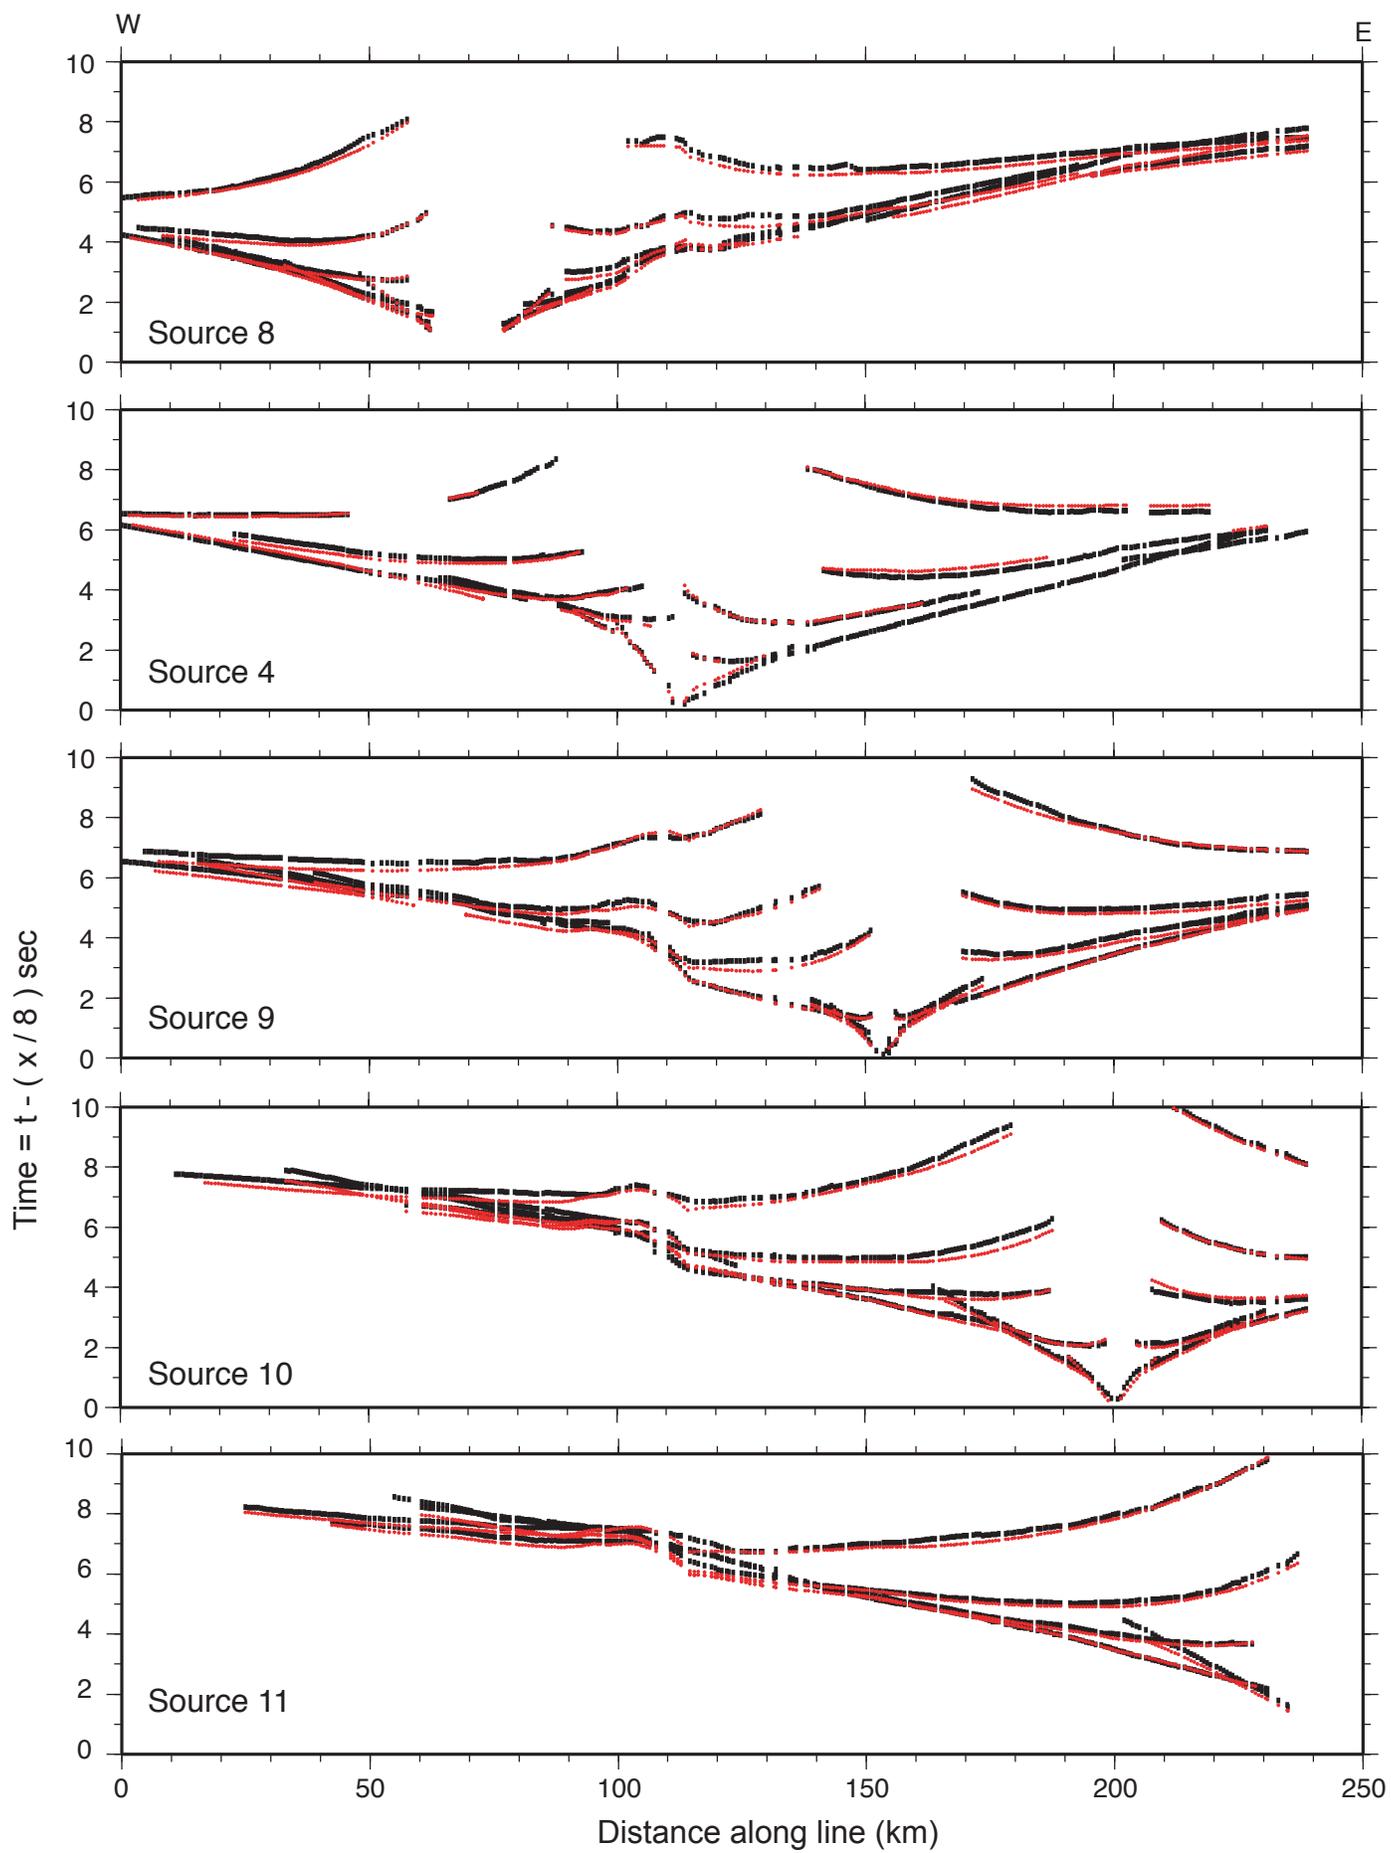

1024

1025 [Figure 10](#) – Subsidence and subsidence rate curves with estimated error bars for the Dead Sea
1026 basin constructed from Sedom Deep-1 borehole Gamma-ray log [*Larsen et al., 2002*]. See text
1027 for details. Subsidence is shown only for the past 7 m.y., because the Hazeva Group (~17-6 Ma)
1028 was undivided. Subsidence rate is plotted at the center of the time interval. Red curve – Scenario
1029 in which the current thickness of the Sedom Salt layer (950 m) is similar to the deposited
1030 thickness. Blue curve – Scenario in which the original thickness of salt layer was 2 km
1031 [*Garfunkel, 1997*] and the thickness decreased linearly to its present value by flow and
1032 diapirism. Grey curve and dot– Approximate subsidence and subsidence rate for the section
1033 described and dated by *Torfstein et al. [2009]*.

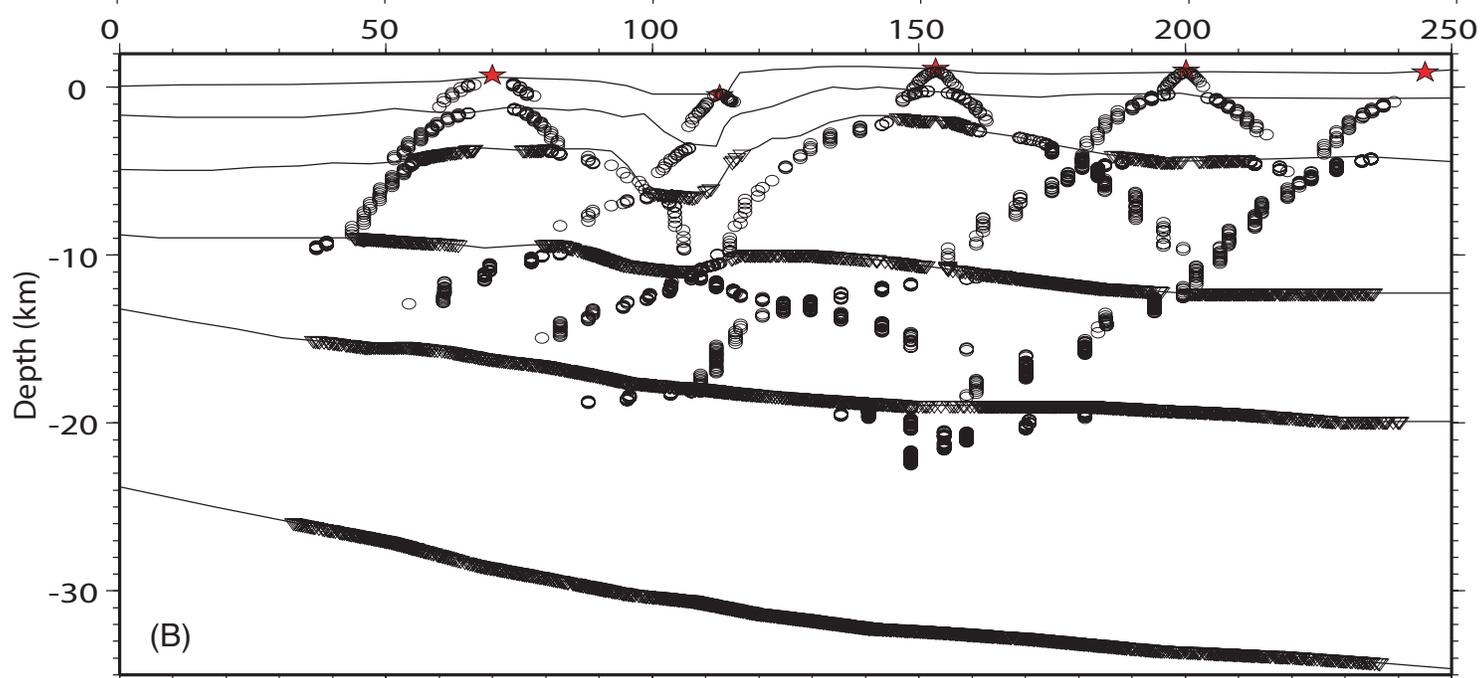

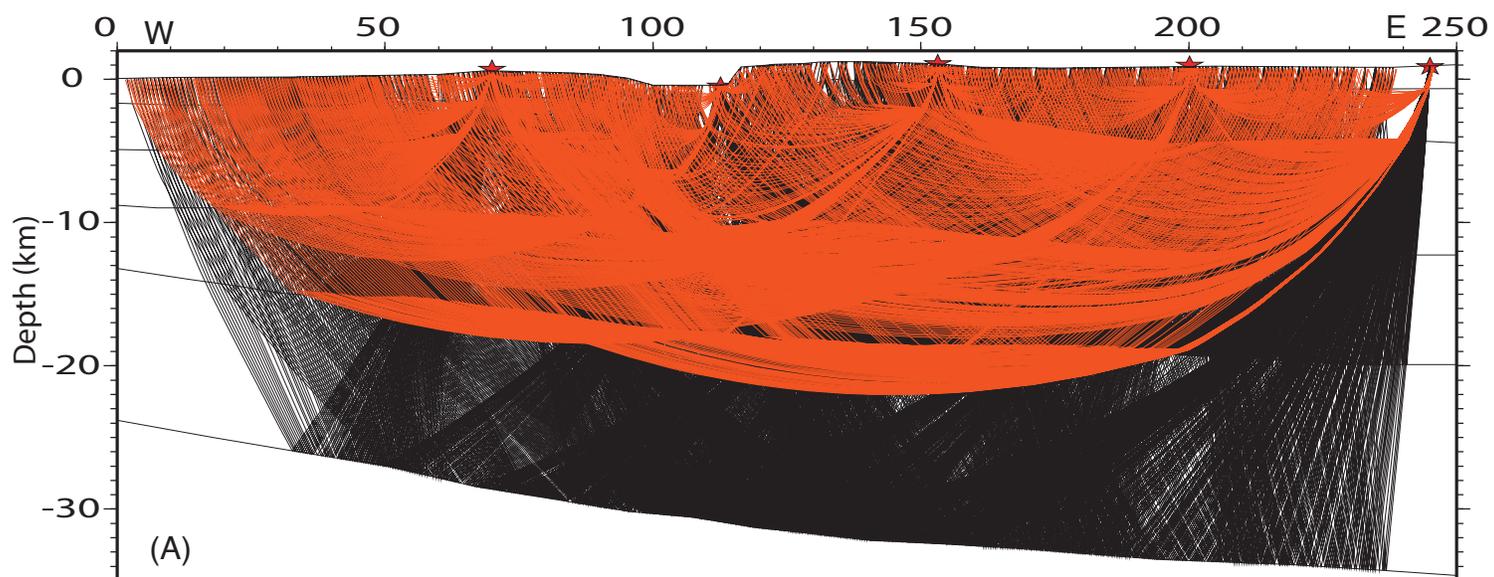

1034

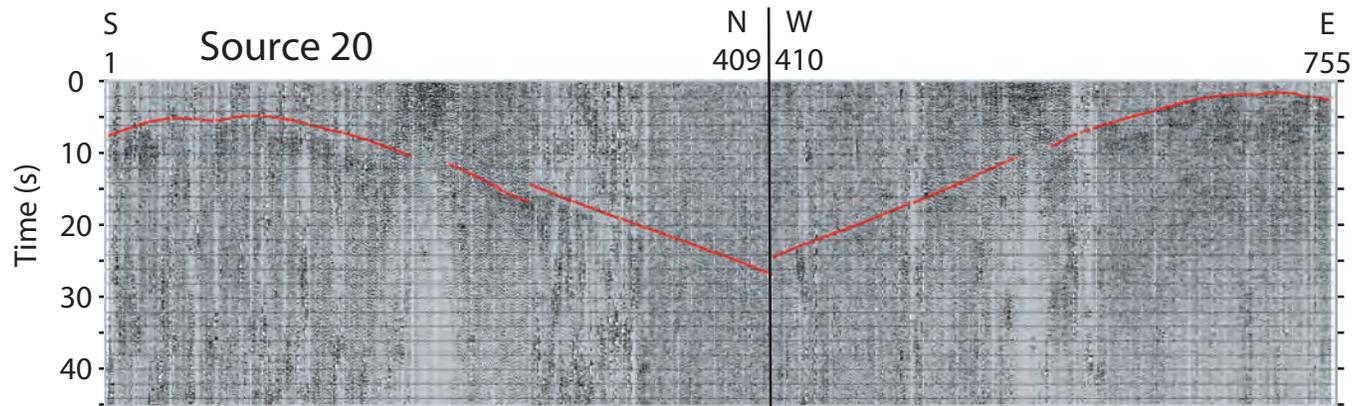

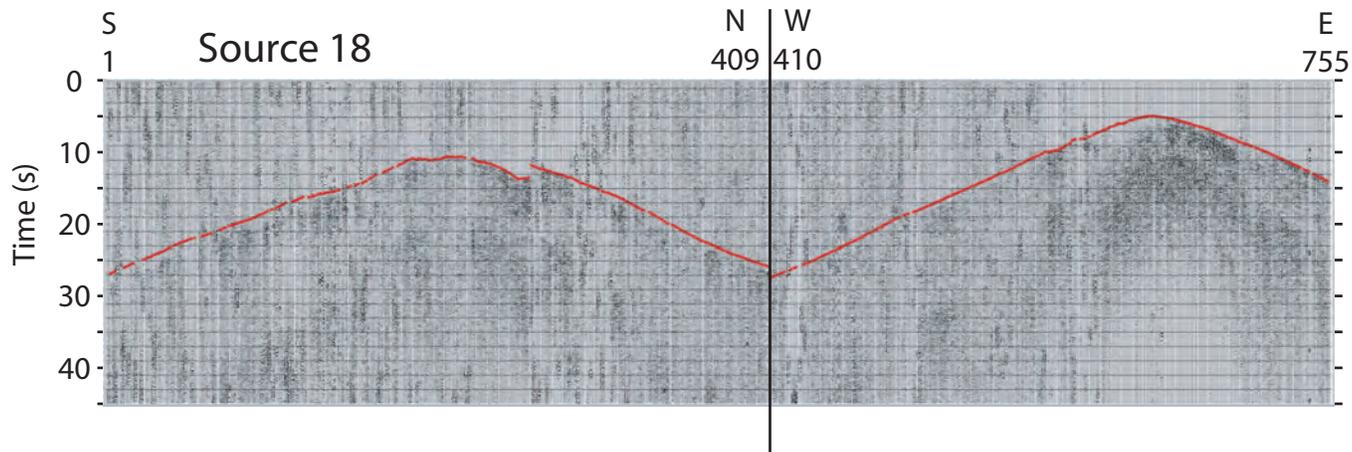

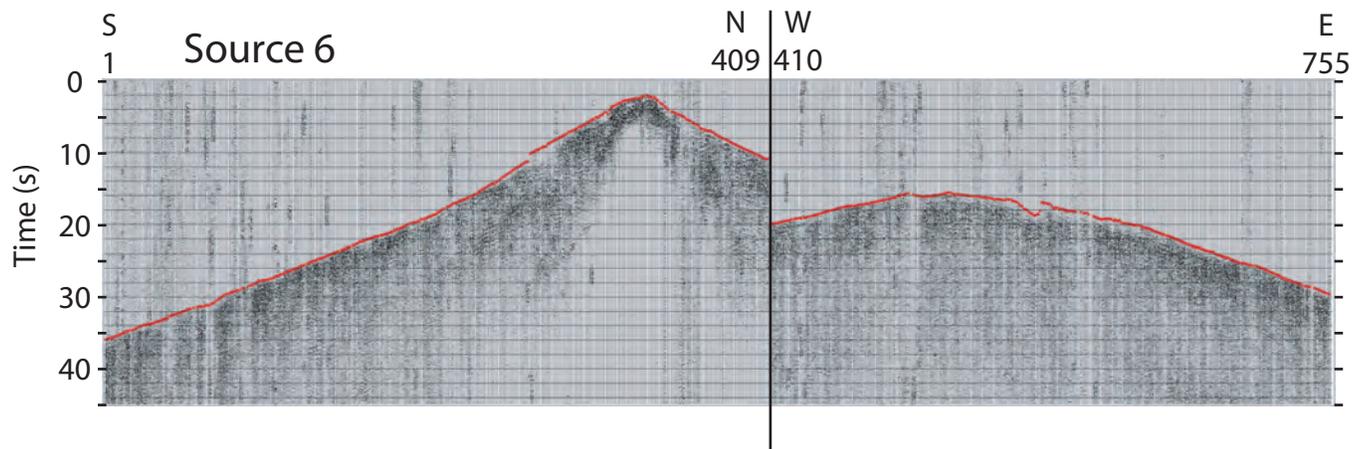

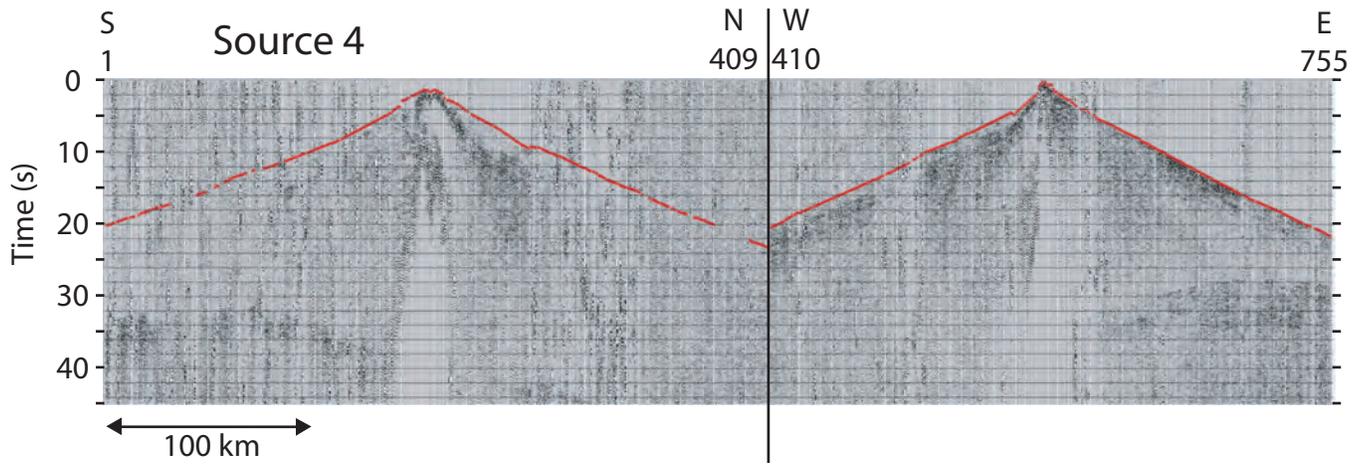

1035 **Figure 11** – (a) Density difference (in 10^3 kg/m^3) between the sediment column within the DSB
1036 and a reference column west of the basin. The density difference results in a 45 MPa difference
1037 in vertical overburden between the basin and the surrounding region on the west in the middle
1038 crust. The difference with the east side is even larger because of the higher elevation and thinner
1039 sediment cover east of the basin relative to west of the basin. (b) Sketch of possible mode of
1040 crustal extension during the past 1 m.y. The activity on the Amazyahu transverse fault (A.F.)
1041 may have decreased. Crustal extension is suggested to be mostly centered in narrow
1042 interconnected mica-rich shear bands and perhaps inclined semi-brittle shear bands above them,
1043 but subsidence is distributed beyond the central deep basin (km 50-130). K.F. – proposed Kalia
1044 fault.

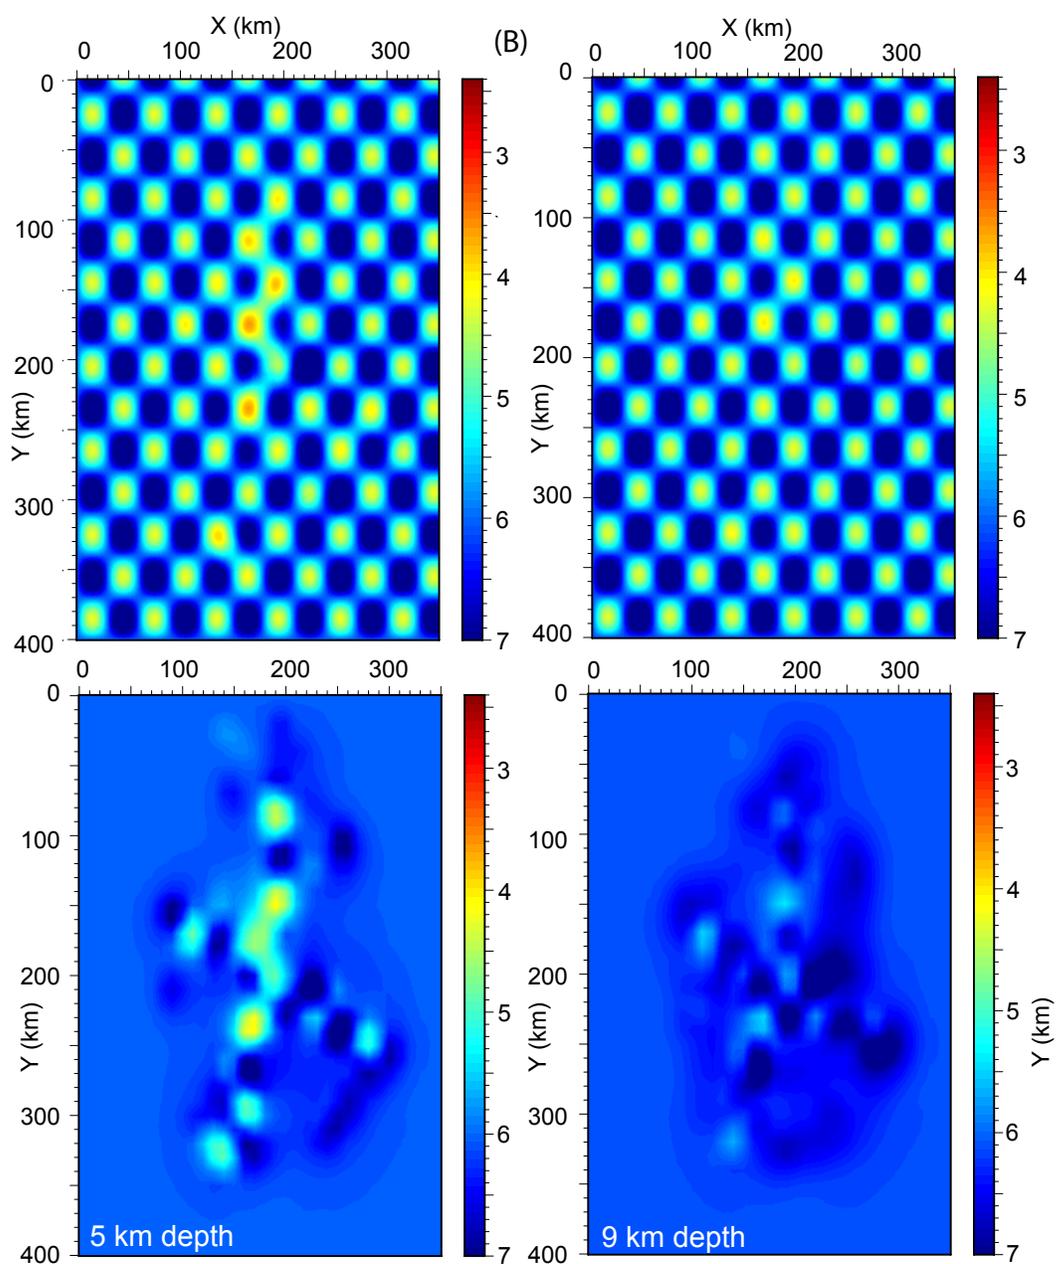

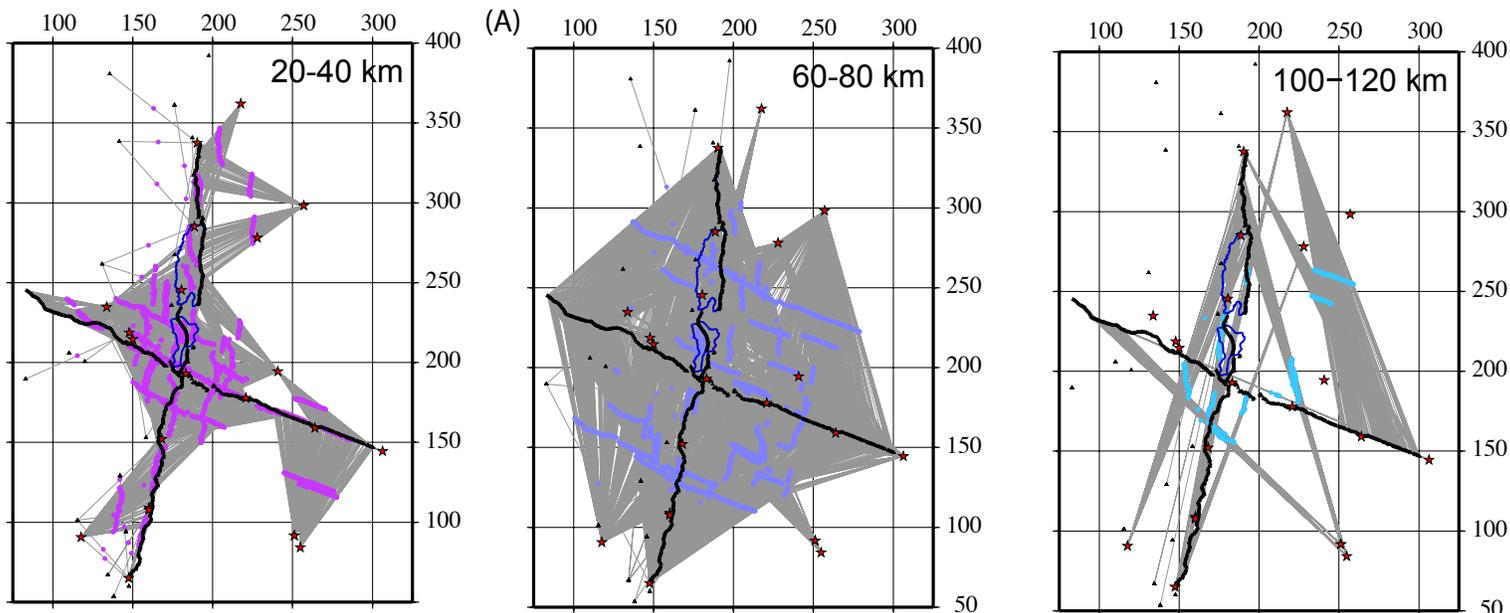

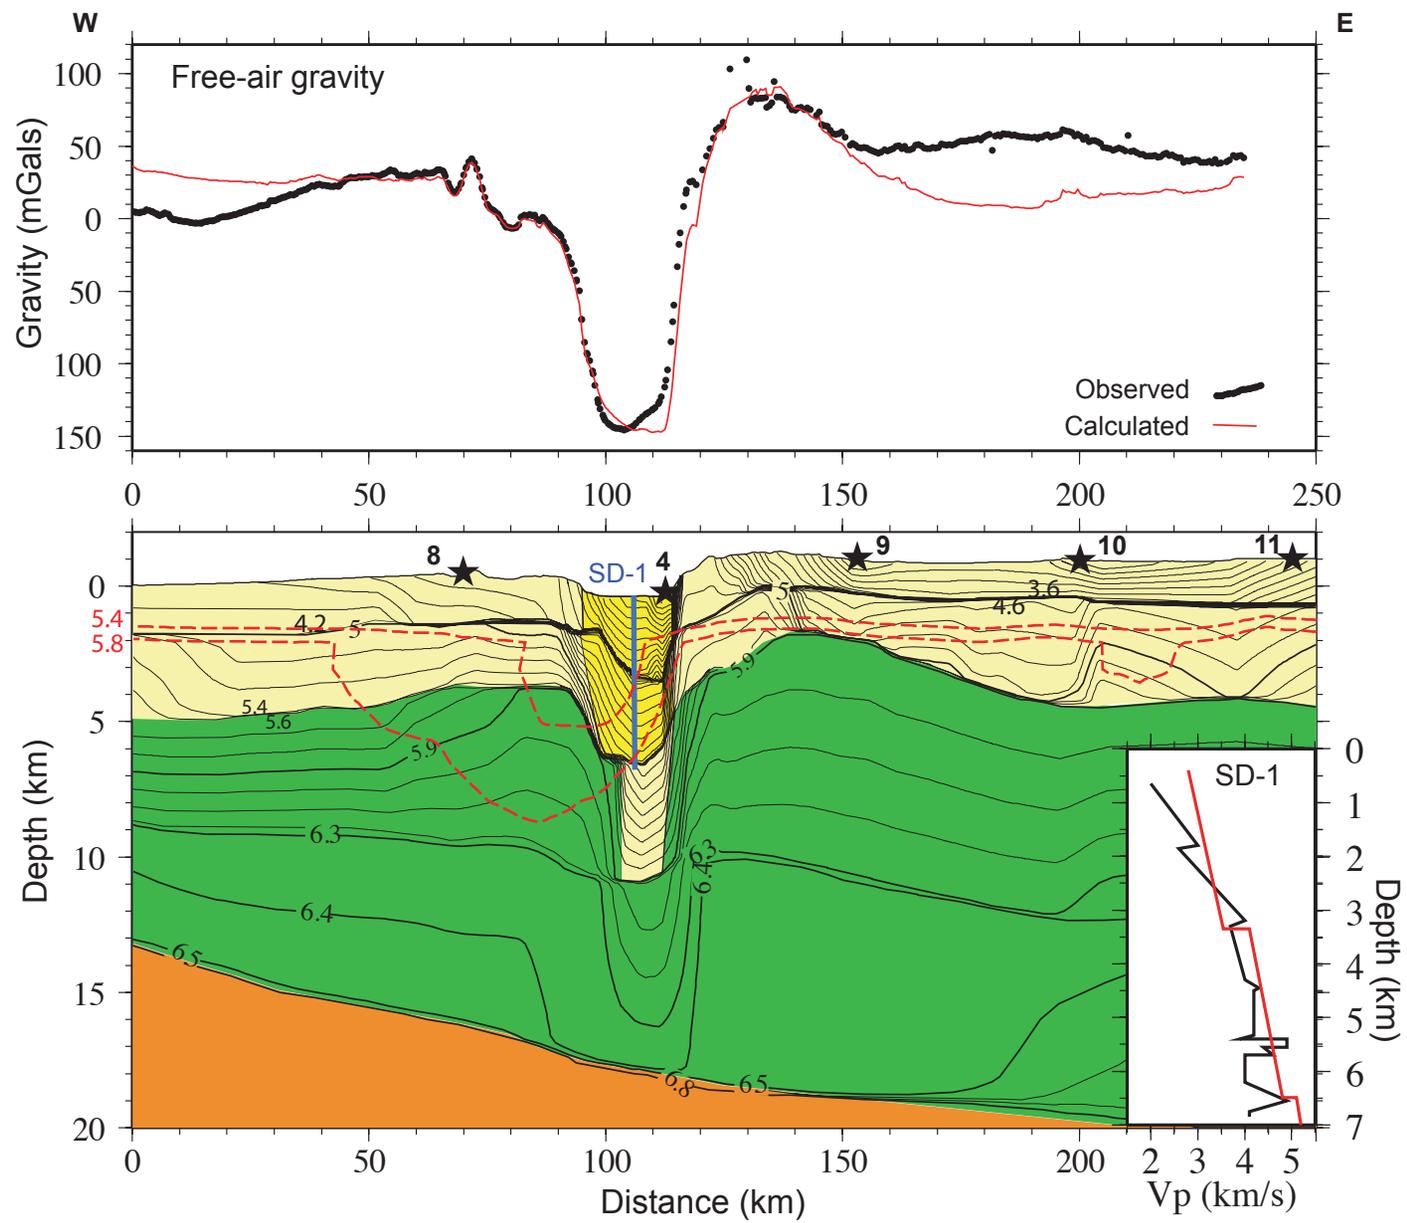

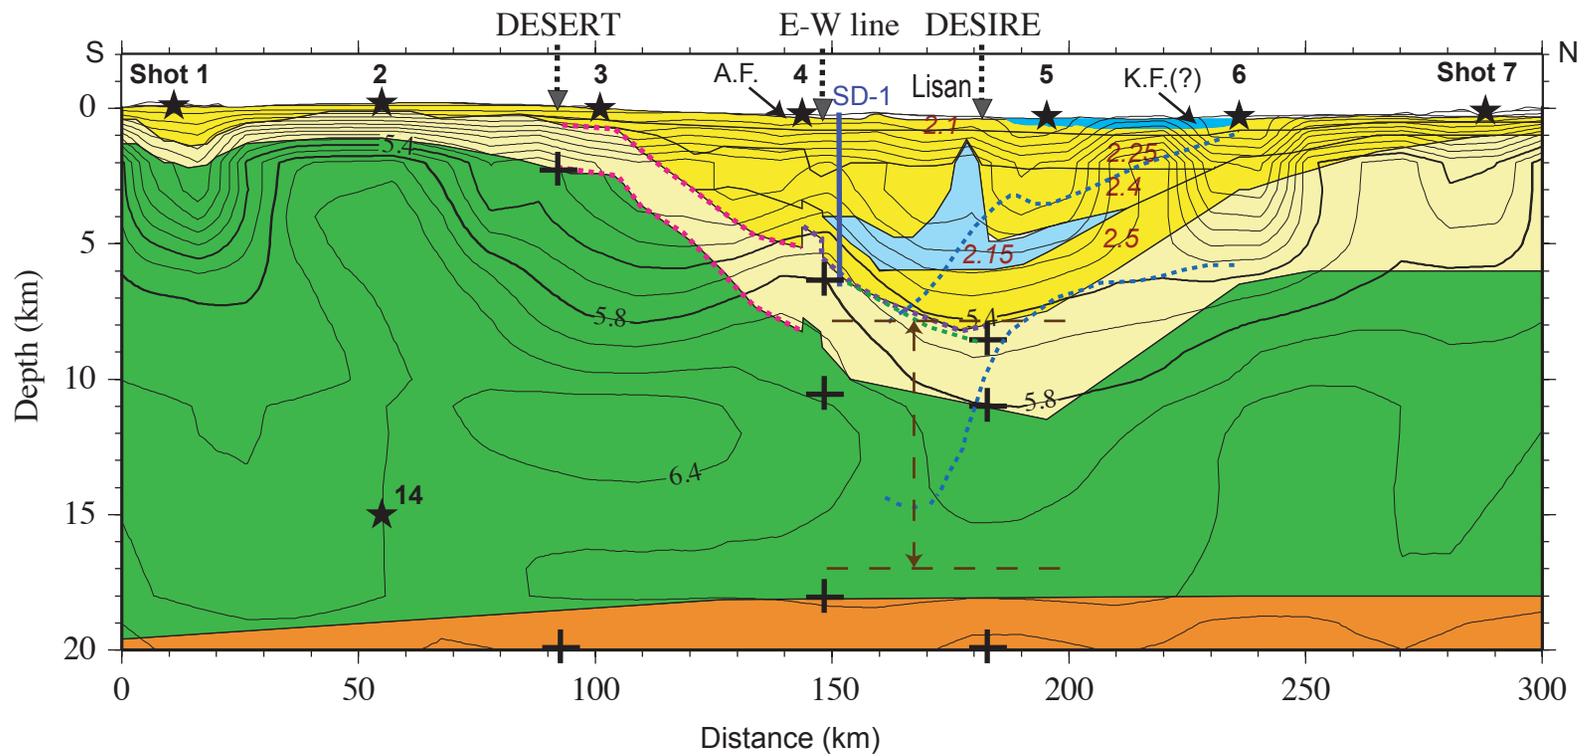

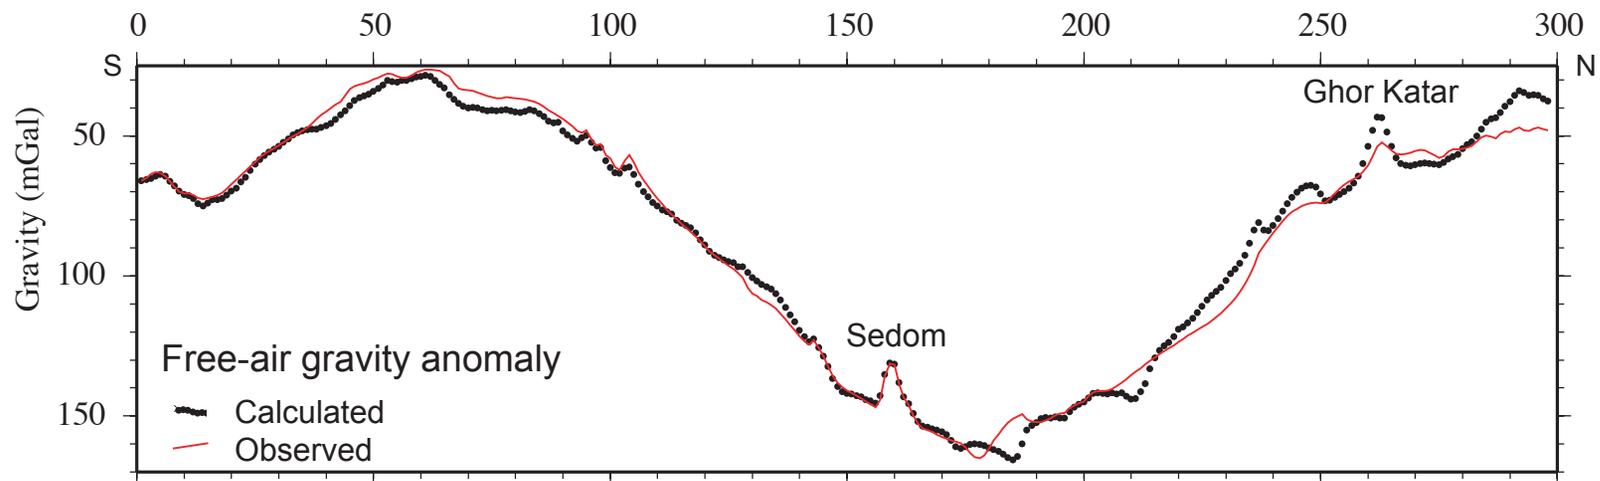

Distance along profile (km)

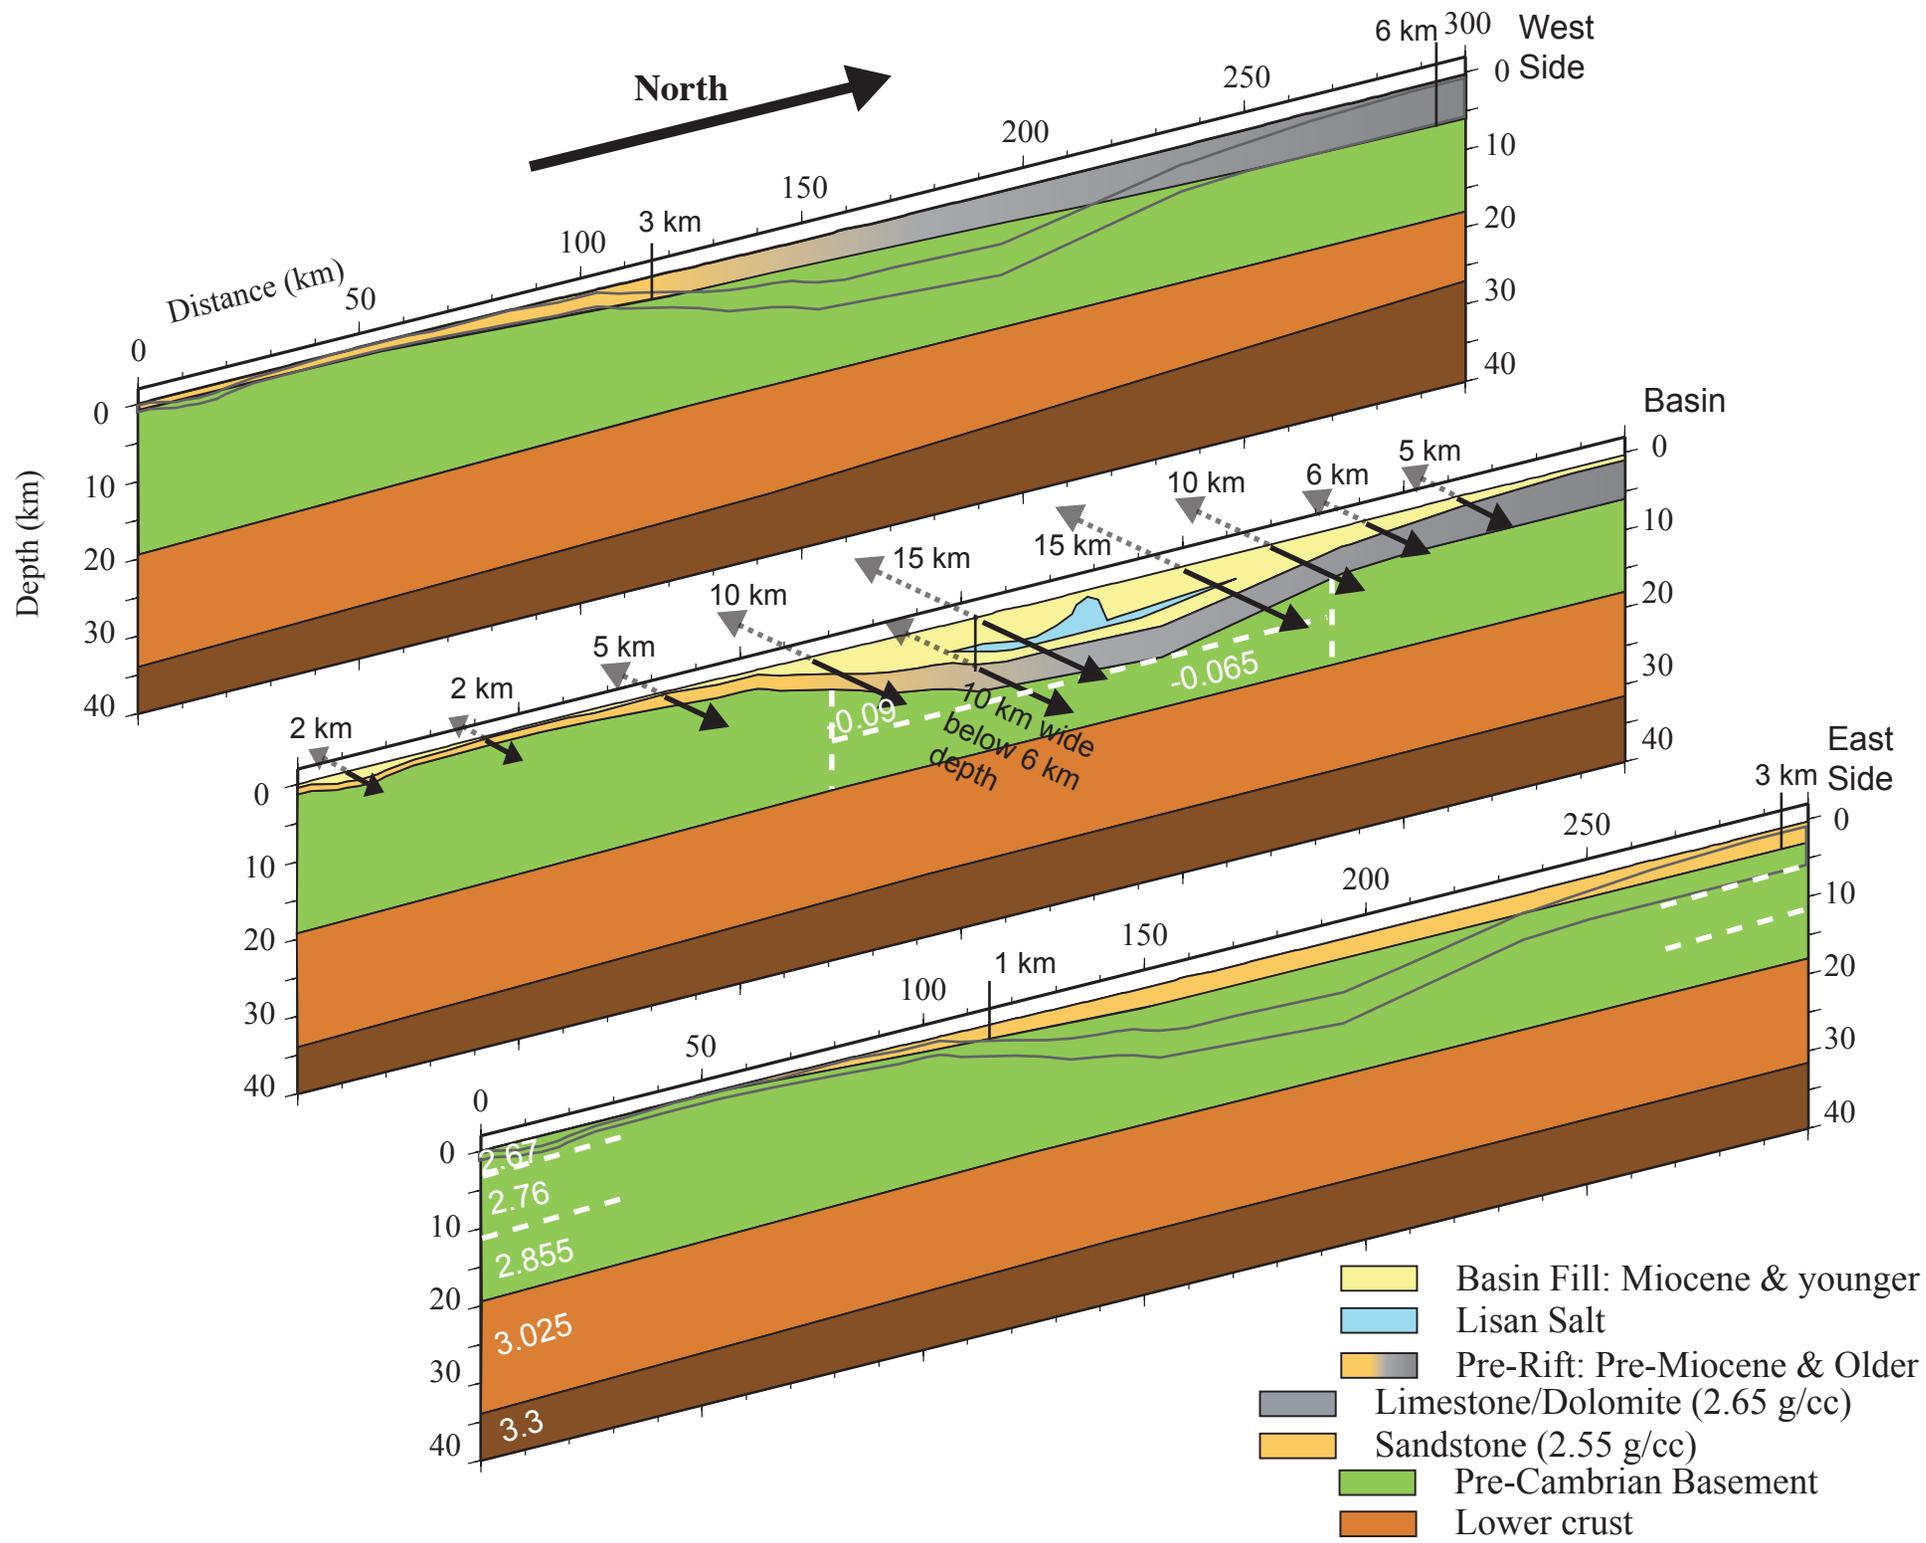

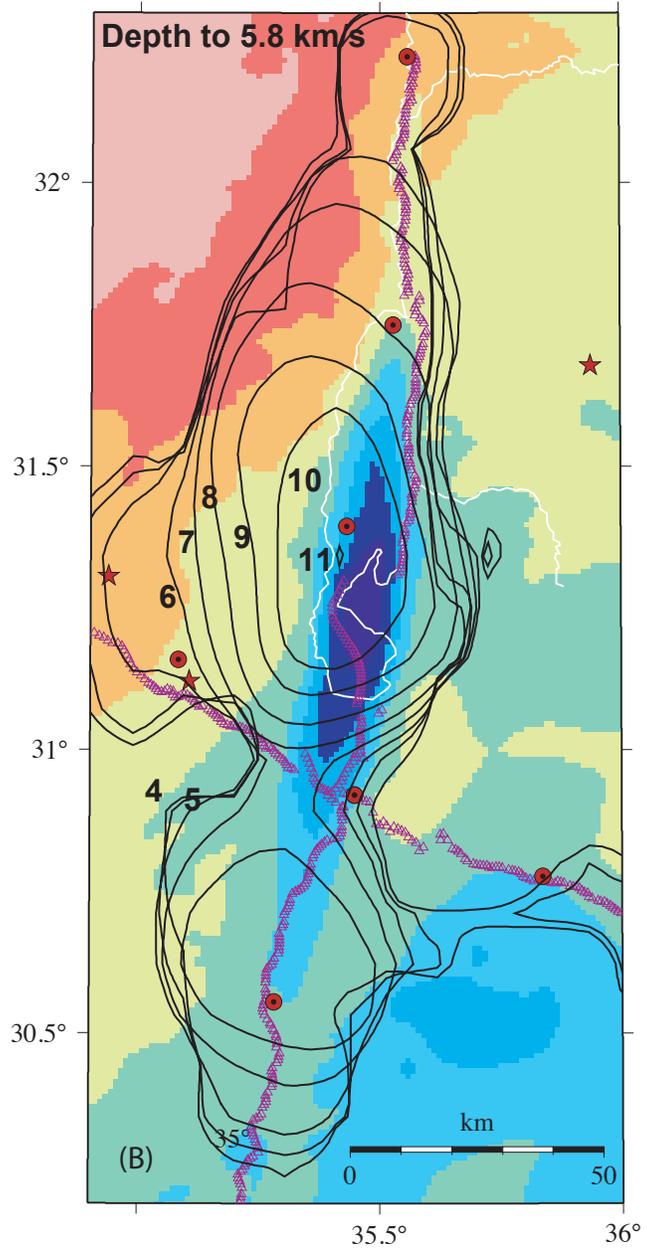

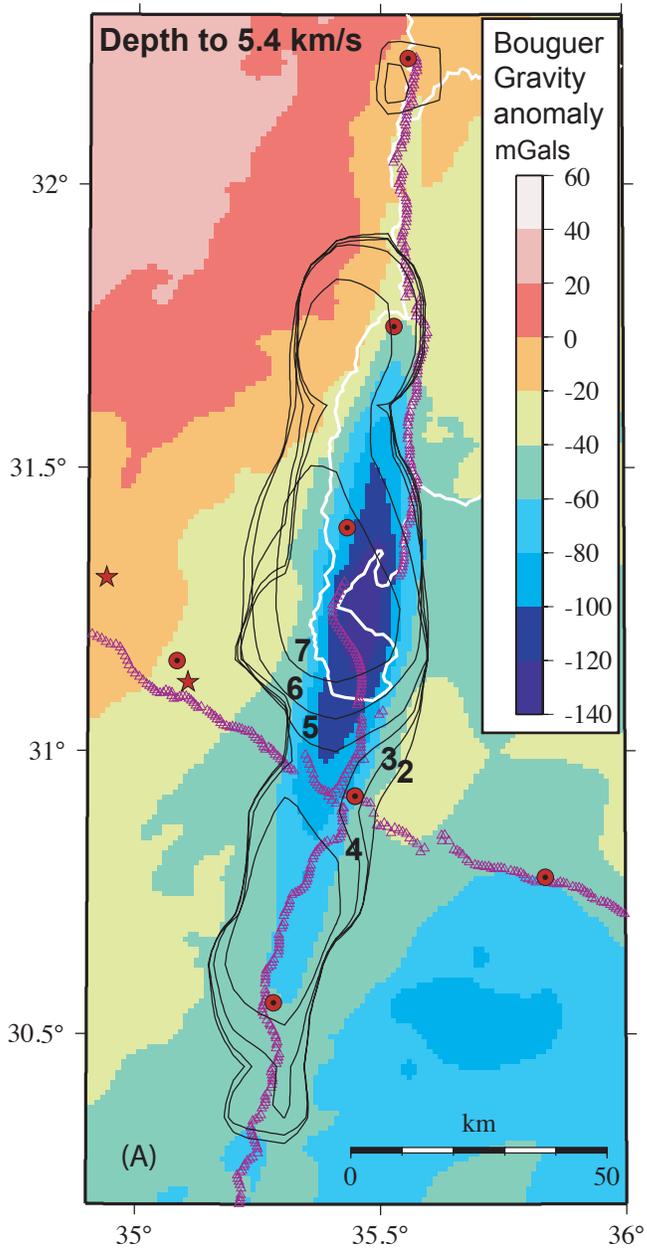

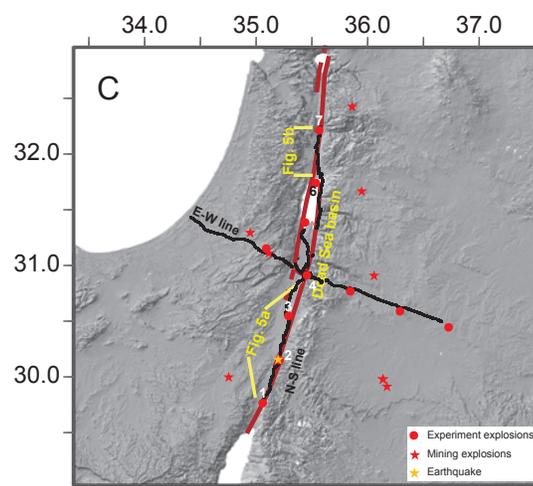

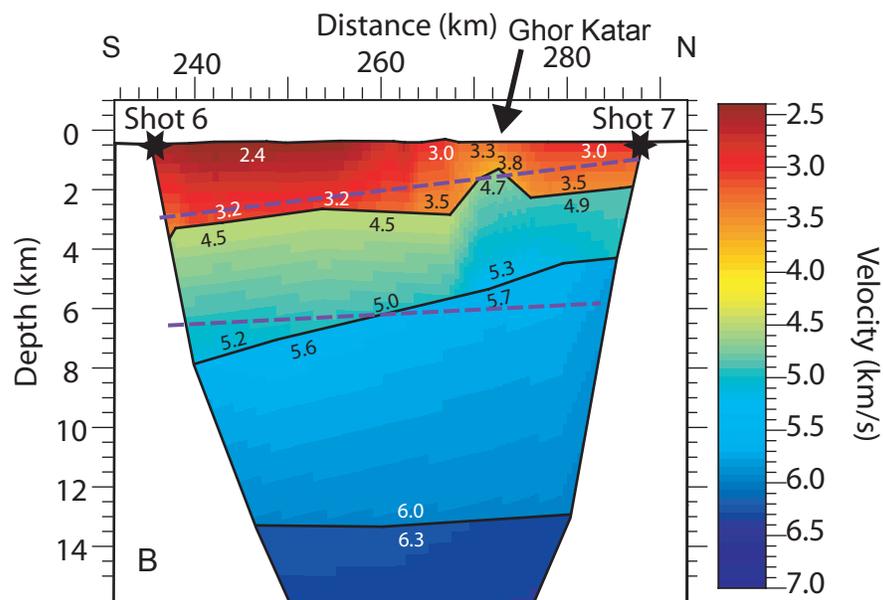

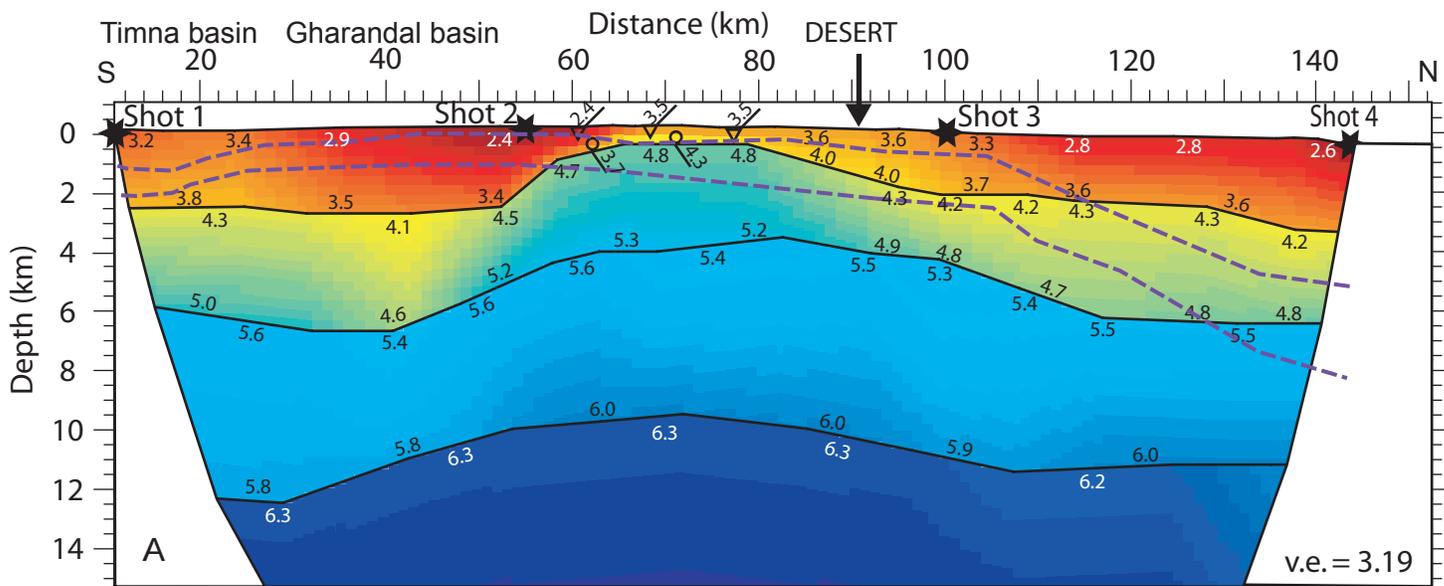

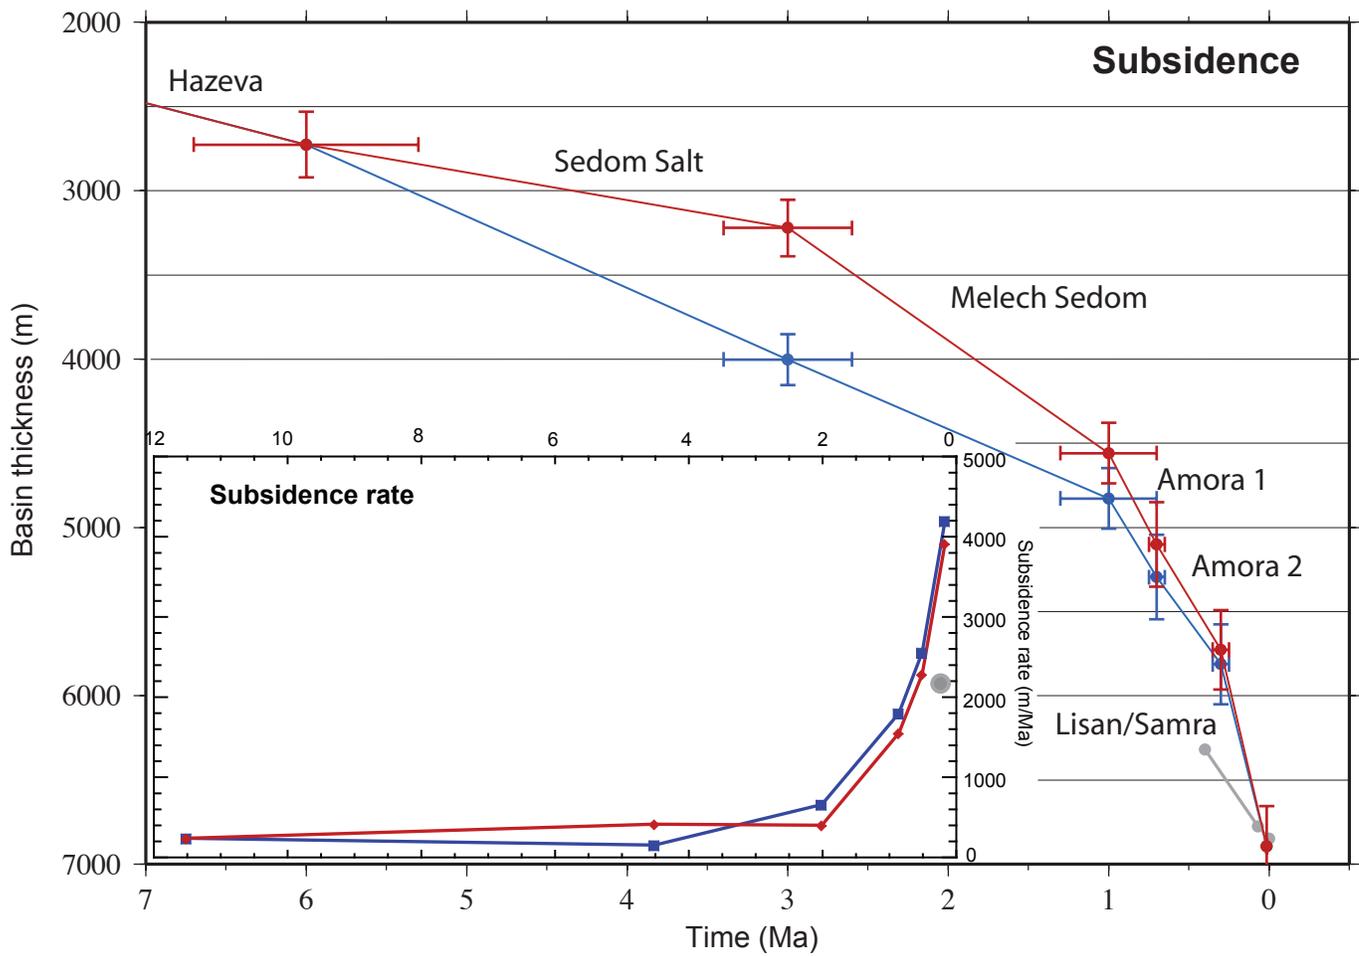

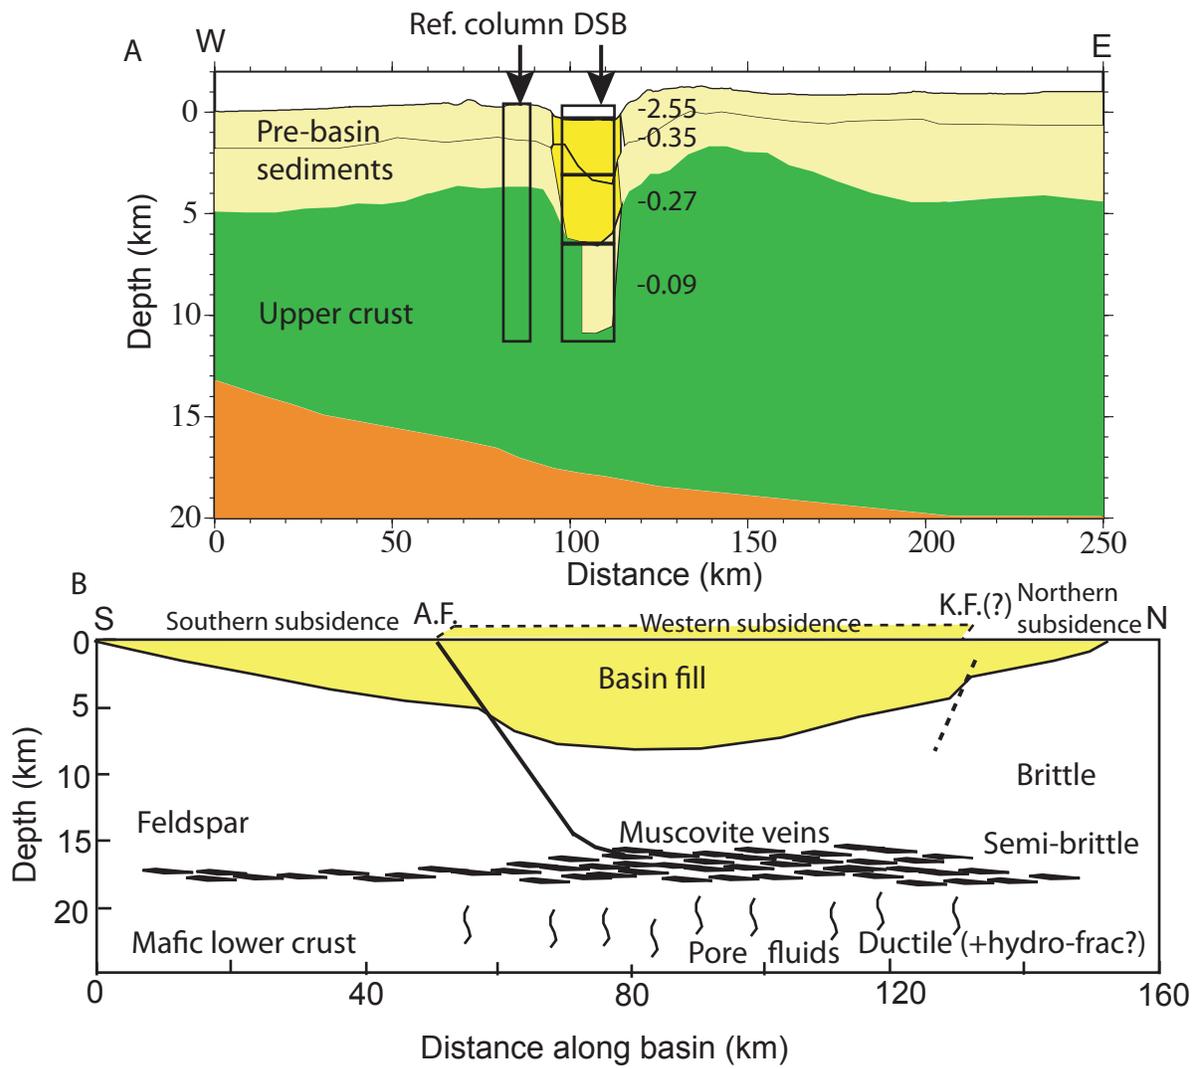

Table 1: Acoustic sources used in the tomographic inversion

Source	Type	Latitude	Longitude	Elevation (m)	# of phase picks	# of 1 st arrivals
1	1000 kg explos.	29.7736	35.04994	63	208	592
2	1000 kg explos.	30.1572	35.18869	189	478	475

* Marine – marine explosion suspended ~50 m below the lake surface. Explos. - explosion

Table 2: Details of the iteration procedure in the tomographic inversion

Tomography		
Iteration # (Cell size)	RMS (ms)	Chi ^2
Starting Model	997.46185	14.8720
Iteration 1 (25x25x5 km)	830.54474	10.2739
Iteration 2 (20x20x5 km)	772.82867	8.8199
Iteration 3 (10x10x1 km)	736.02740	7.9627
Iteration 4 (10x10x1 km)	631.39069	5.8002
Iteration 5 (10x10x1 km)	546.15936	4.3257
Iteration 5 (10x10x1 km)	521.26697	3.9322
Wide Angle	RMS (ms)	Chi ^2
East-West Profile	145.0	2.097
North-South Profile	469.0	22.042
Gravity	Error (mGal)	
East-West Profile	22.255*	
North-South Profile	4.22	

*Model is solely based on conversion of *P* wave velocity structure to density structure

Table 3: Parameters used to correct for sediment porosity

Lithology	Phi value	C (1/km)
Sand	0.490	0.270
Quartz Sand	0.620	0.360
Shale-Sand	0.560	0.390
Shale-Clay	0.630	0.510
Carbonate/Calcite	0.240	0.540
*Marl	0.435	0.525
*Sand-Marl	0.4918	0.3953

Notes:

*Marl = 50% Shale-Clay + 50% Carbonate/Calcite

*Sand-Marl = 50% Sand + 32.5% Shale-Clay + 17.5% Carbonate/Calcite
